The line of Toldt is incised and the colon is mobilized inferiorly (Fig. 107.20). The splenocolic and lienorenal ligaments are incised toward the diaphragm to the level of the gastric cardia, allowing for full medial rotation of the spleen away from the surgical field. Care should be taken to avoid injury to the stomach and diaphragm at this stage. A sudden loss of pneumoperitoneal pressure with increases in ventilation pressures may signify diaphragmatic perforation. With the spleen rotated away and the tail of the pancreas dissected off, the left adrenal gland will come into view. Occasionally, especially in patients with Cushing syndrome, dense retroperitoneal fat may obscure the adrenal gland. A laparoscopic ultrasound probe can be inserted through the 10- to 12-mm port for localization of the adrenal gland.

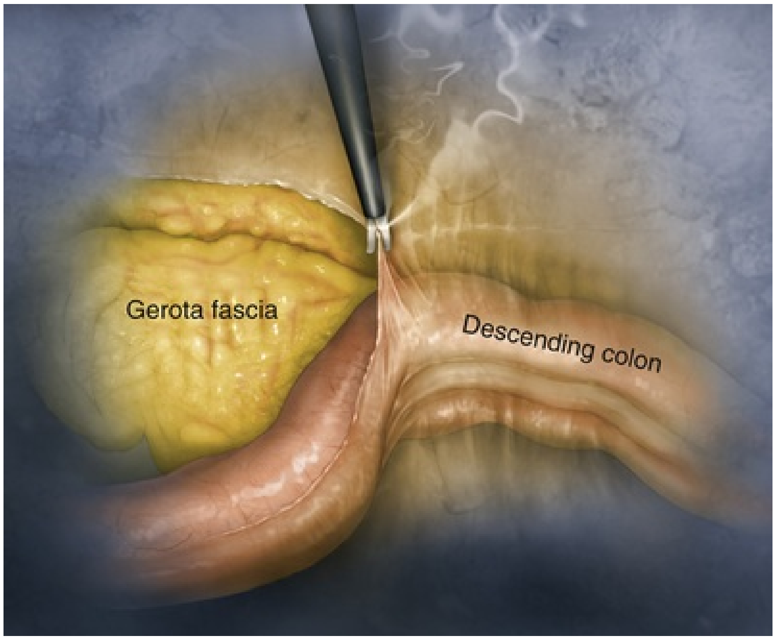

FIG. 107.20 Transperitoneal laparoscopic adrenalectomy. Incision of the line of Toldt and medial dissection of the left colon with cautery endoscopic scissors.

Ligation of Left Adrenal Vein and Mobilization of the Left Adrenal Gland.

The left renal vein is identified and traced along its superior border to reach the point of entry of the left adrenal vein (Fig. 107.21). The left adrenal vein is carefully isolated and ligated. It is advisable to place at least two clips on the stay side of the adrenal vein (Fig. 107.22). Care has to be taken to avoid any upper pole branch of the left renal artery, which may lie behind the adrenal vein. It is also important to recognize that the inferior phrenic vein may occasionally join the adrenal vein before its entry into the left renal vein. The adrenal arterial supply is divided with either cautery or a harmonic scalpel as the adrenal is dissected free (Figs. 107.23 and 107.24). **Grasping on the adrenal gland should be avoided because the gland is fragile and tears easily, leading to increased intraoperative bleeding.**

Closure.

Once the adrenal gland is freed, it is placed in an endoscopic bag and removed via the 10- to 12-mm port (Fig. 107.25). Pneumoperitoneal pressure is reduced to 5 mm Hg and the surgical bed inspected for hemostasis. All port sites larger than 5 mm are closed in layers with fascial approximation and skin closure.

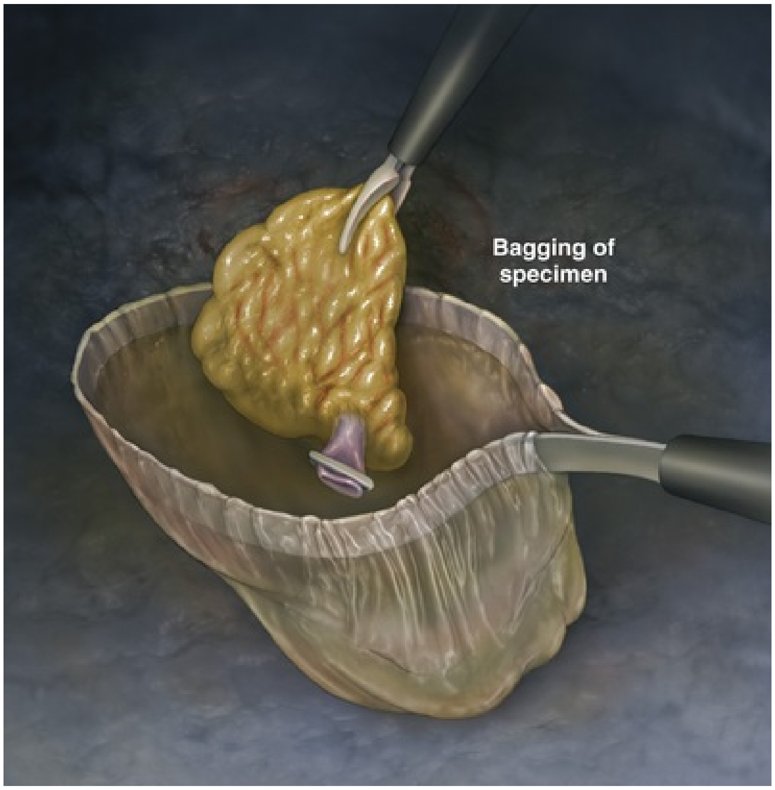

FIG. 107.25 Transperitoneal laparoscopic adrenalectomy. Placement of specimen in endoscopic extraction sac.

Transperitoneal Lateral Approach: Right Adrenalectomy

The port configuration for transperitoneal laparoscopic lateral right adrenalectomy is shown in Fig. 107.26. An additional 2- or 5-mm port sited most superomedially is used for liver retraction. After creation of pneumoperitoneum, the first step is to mobilize the liver by dividing the triangular ligament laterally and inferiorly. The liver is then retracted anterosuperiorly using the shaft of a 2- or 5-mm laparoscopic ratcheted locking forceps (Fig. 107.27). The lateral parietal peritoneum is grasped by the forceps, creating an assistant-free self-retaining retraction of the liver. A Kocher maneuver is then performed to mobilize the second part of the duodenum. This permits the visualization of the inferior vena cava and the right adrenal gland. The short right adrenal vein can be identified as it joins the inferior vena cava. The rest of the dissection is similar to that described on the left side.

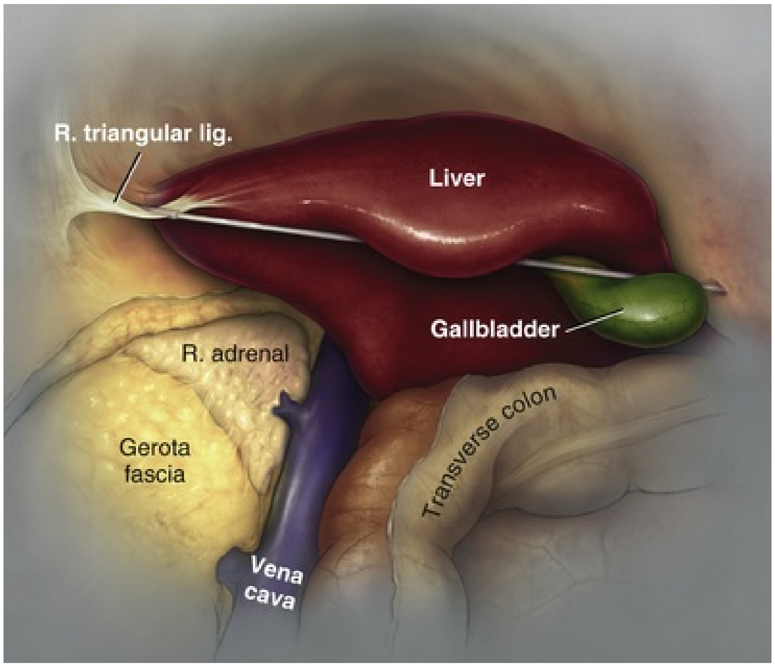

FIG. 107.27 A 2-mm trocar and locking grasping forceps can be used instead of a larger-caliber fan retractor to act as a self-retaining liver retractor. It is important that the trocar be placed just below the xiphoid process to ensure adequate retraction. *lig,* Ligament; *R,* right.

Gasless Laparoscopic Transperitoneal Approach

Pneumoperitoneum is associated with several negative hemodynamic, metabolic, neurologic, and humoral effects. These include decreased venous return and cardiac output, elevated systemic arterial blood pressure, increased inspiratory and expiratory airway pressures and end-tidal carbon dioxide levels, decreased renal blood flow, and possible gas embolism. Pneumoperitoneum is thus contraindicated in certain groups of patients with preexisting cardiac, pulmonary, or neurologic diseases.

Giraudo et al. (2009) described their gasless laparoscopic adrenalectomy techniques using an abdominal wall lifting platform. The LaparoTenser (L&T Lucini, Milan, Italy) (Fig. 107.28) is used as an abdominal wall retractor, with two curved needles placed in the subcutaneous tissue of the anterolateral abdominal wall. The intraperitoneal space is created by lifting the abdominal wall, which eliminates the need for pneumoperitoneum. Three or four trocars are then inserted and dissection of the adrenal gland proceeds in a manner similar to that described earlier. The main suggested benefit of this technique is that it allows laparoscopic transperitoneal adrenalectomy to be performed as an alternative to open surgery in patients with contraindications to pneumoperitoneum.

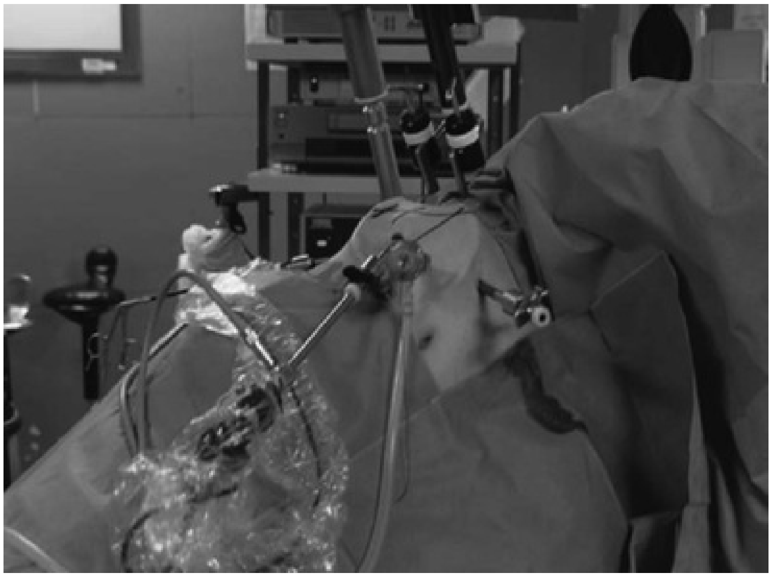

FIG. 107.28 The LaparoTenser (L&T Lucini, Milan, Italy). (From Giraudo G, Pantuso G, Festa F, et al.: Clinical role of gasless laparoscopic adrenalectomy. *Surg Laparosc Endosc Percutan Tech* 19:329–332, 2009.)

Retroperitoneal Approach

Laparoscopic retroperitoneal adrenalectomy can be performed using either the prone or the lateral approach. The main advantage of the retroperitoneal approach is that entry into the peritoneum is avoided and thus complications such as visceral and bowel injuries are minimized. In the absence of pneumoperitoneum, hemodynamic and respiratory morbidities are also reduced. In addition, dense intraperitoneal adhesions arising from previous surgery or inflammation are averted by operating in the retroperitoneum. The main disadvantage of the retroperitoneal approach is the limited working space that makes dissection of large tumors difficult. Furthermore, because of the smaller skin surface area for port placement, the risk of improper port placement leading to colonic injury is increased (Liapis et al., 2008). Finally, the lack of anatomic landmarks and the abundant retroperitoneal adipose tissues may pose a significant challenge to surgeons inexperienced with the retroperitoneum.

The main advantage of the lateral approach over the posterior approach is the ease of conversion into the transperitoneal approach should difficulties be encountered. In contrast, the prone retroperitoneal approach allows for bilateral adrenalectomy without patient repositioning.

Retroperitoneal Lateral Adrenalectomy: Left Adrenalectomy

Positioning and Ports Placement.

The patient is placed in the lateral position with the left side up with a kidney rest under the body and the operating table flexed to accentuate the left flank. A 1.5-cm incision is made near the tip of the 12th rib under the 11th rib. The underlying muscle and fasciae are divided with cautery until the lumbodorsal fascia is visible. This lumbodorsal fascia is then incised sharply and a finger is inserted to confirm access into the retroperitoneal space. The inner surface of the 12th or 11th rib should be palpable superiorly and the iliac crest felt inferiorly. Blunt finger dissection is used to create a plane between the psoas muscle and the posterior Gerota fascia by sweeping the kidney anteriorly and the peritoneum medially. This retroperitoneal space is then widened with a retroperitoneal dissection balloon inflated under direct vision by inserting the laparoscope into its transparent shaft. The balloon dissector is directed along the posterior abdominal wall in a cephalic direction. The psoas muscle is usually identifiable, and this serves as a landmark for longitudinal orientation. A balloon-tip trocar is secured in position into this space and insufflation of the retroperitoneum is generated. A 5- or 10-mm trocar is placed at the angle of the paraspinal muscle and the origin of the 12th rib. Another 5- or 10-mm trocar is placed about two fingerbreadths above the iliac crest near the anterior superior iliac spine (Fig. 107.29).

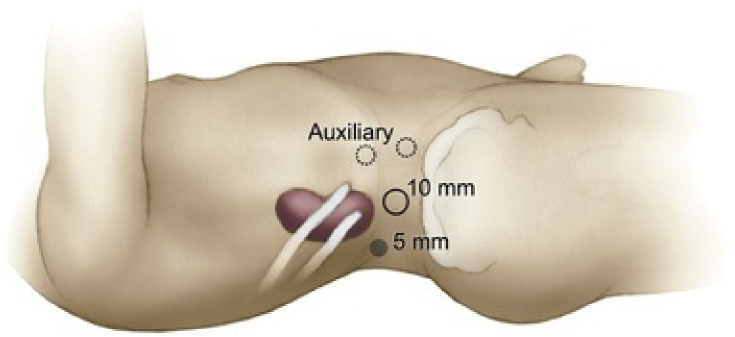

FIG. 107.29 Trocar placement for retroperitoneal laparoscopy. The *dotted circles* represent alternative sites for placement of a third port.

Ligation of Left Adrenal Vein and Mobilization of Left Adrenal Gland.

With use of medial dissection, the great vessels can be identified by their pulsation and their course parallel to the psoas. The renal hilum is then identified by the pulsation of the posteriorly situated renal artery. The superior border of the renal artery is dissected to expose the left adrenal vein as it courses anterior and cephalad to the renal artery toward the inferomedial border of the left adrenal gland (Fig. 107.30). The left adrenal vein is subsequently doubly clipped and ligated (Fig. 107.31). Small arterial branches arising from the aorta are ligated with cautery or a harmonic scalpel, mobilizing the medial border of the gland. The inferior and lateral borders of the gland are then mobilized in a similar manner from the upper pole of the left kidney. Finally, the anterior and superior borders of the gland are freed. The inferior phrenic vein may course along the anteromedial border of the gland to join the left adrenal vein. If encountered, it could be clipped and ligated.

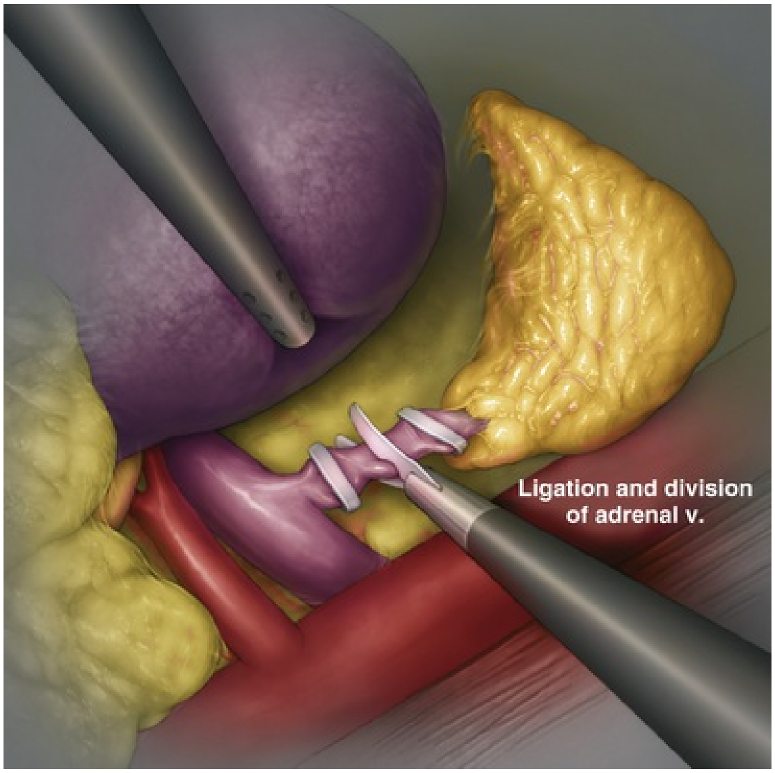

FIG. 107.31 Retroperitoneal laparoscopic adrenalectomy. Ligation and division of left adrenal vein. The kidney is dissected away from the adrenal gland. *v,* Vein.

Closure.

The specimen is placed in an endoscopic bag and extracted through a 10-mm port. After ensuring adequate hemostasis, the trocar sites are closed in the standard fashion as described earlier.

Retroperitoneal Lateral Adrenalectomy: Right Adrenalectomy

The right adrenalectomy is performed in a similar fashion, dissecting cephalad along the inferior vena cava to reach the renal hilum and right adrenal vein. The anatomic relationships of this approach are illustrated in Fig. 107.32.

Robot-Assisted Adrenalectomy

Currently, the da Vinci Surgical System (Intuitive Surgical, Sunnyvale, CA) is the dominant commercially available platform for robotic surgery, and the majority of adrenalectomies were performed using the da Vinci Surgical System. Since the first robot-assisted adrenalectomy in 1999, many centers around the world have jumped onto the bandwagon of robot-assisted adrenalectomy. The main benefits of the robotic system over conventional laparoscopy lie in superior ergonomics, three-dimensional (3D) magnification of the operative field, tremor filtering, and enhanced degrees of freedom of the EndoWrist (Intuitive Surgical, Sunnyvale, CA) instruments. These advantages of the robotic platform render it ideal in handling the fragile adrenal gland in a deep narrow space surrounded by major vessels and viscera, where injury may lead to catastrophic consequences.

Robot-Assisted Lateral Transperitoneal Adrenalectomy

After insertion of a nasogastric tube and urinary catheter, the patient is positioned in an oblique lateral position with the affected side elevated on a kidney rest at an angle of 30 to 45 degrees from the table. The bony prominences are padded and the patient is strapped securely onto the table. The table is then tilted in the opposite direction to achieve a supine position for port placement. A longitudinal 1.2-cm supraumbilical incision is made and pneumoperitoneum is established with a Veress needle. A 12-mm optical port is inserted for the camera for the S/Si model. The 12-mm port is replaced by a 8-mm robotic port in the Xi model. Two 8-mm robotic ports and a 12-mm assistant port are inserted under vision in the configuration shown in Fig. 107.33. For right adrenalectomy, an additional 5-mm port is inserted just inferior to the xiphoid process for liver retraction (Fig. 107.34). In general, the distance between the camera and each robotic port should be at least 8 cm to reduce instrument clashing internally and robotic arms clashing externally. The table is now tilted so that the patient lies in a full lateral position with the affected side upward. To facilitate access to the upper areas of the retroperitoneum, the robot is docked at an angle at the head of the table for the S/Si model as outlined in Fig. 107.35. For the Xi model, because of the rotating boom technology, there is more flexibility for the docking of the robot depending on the user's operating room setup.

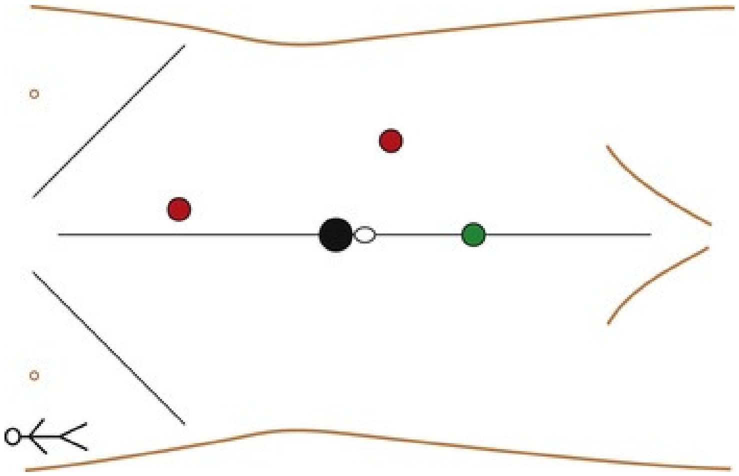

FIG. 107.33 Left robotic adrenalectomy trocar placement. A total of four ports are placed: one 12-mm camera port (●), one 12-mm assistant port (🟢), and two 8-mm robotic arm ports (🔴). The distance between each port should be at least 8 cm.

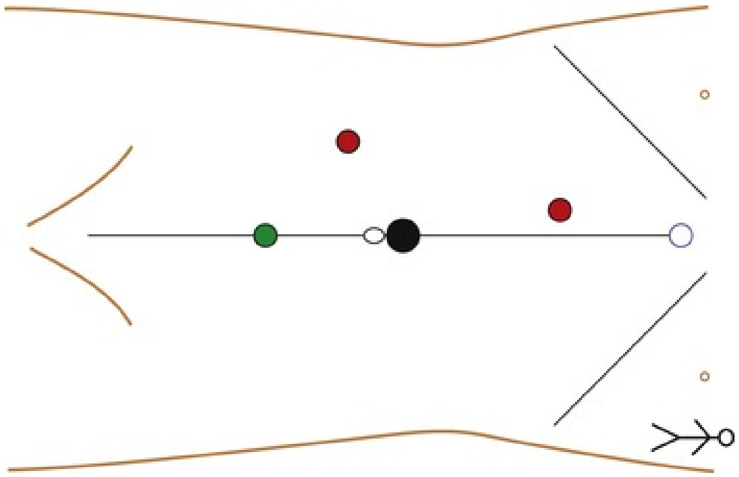

FIG. 107.34 Right robotic adrenalectomy trocar placement. A total of five ports are used: one 12-mm camera port (●), one 12-mm assistant port (🟢), two 8-mm robotic arm ports (🔴) are established, and to retract the liver, a 5-mm trocar (○) is placed with a retraction device.

The dissection and mobilization of the adrenal gland are similar to the transperitoneal laparoscopic techniques described earlier.

Robot-Assisted Posterior Retroperitoneal Adrenalectomy

The patient is placed in a prone jackknife position using a Wilson frame. A small transverse incision is made just below the tip of the 12th rib and the retroperitoneal space is entered sharply. This space is further developed bluntly with a finger or with a dissecting balloon under vision if desired. A 12-mm optical port or 8-mm robotic port is designated as the camera port is anchored in place. Pneumoretroperitoneum was established with CO_2 insufflation. Two other 8-mm robotic ports were then placed on both sides of the camera port at least 8 cm apart, with the lateral port placed just below the line of 12th rib and the medial port in the subcostal location about 3 cm below the junction of the 12th rib and the paraspinous muscles. A 5-mm or 10- to 12-mm assistant port was placed lateral and inferior to the camera port (Fig. 107.36). The Gerota retroperitoneal fascia may have to be taken down carefully, avoiding injuring surrounding structures or violating the peritoneum laterally over the liver or spleen to create adequate space for ports placement. The surgical robot is docked from the patient's head.

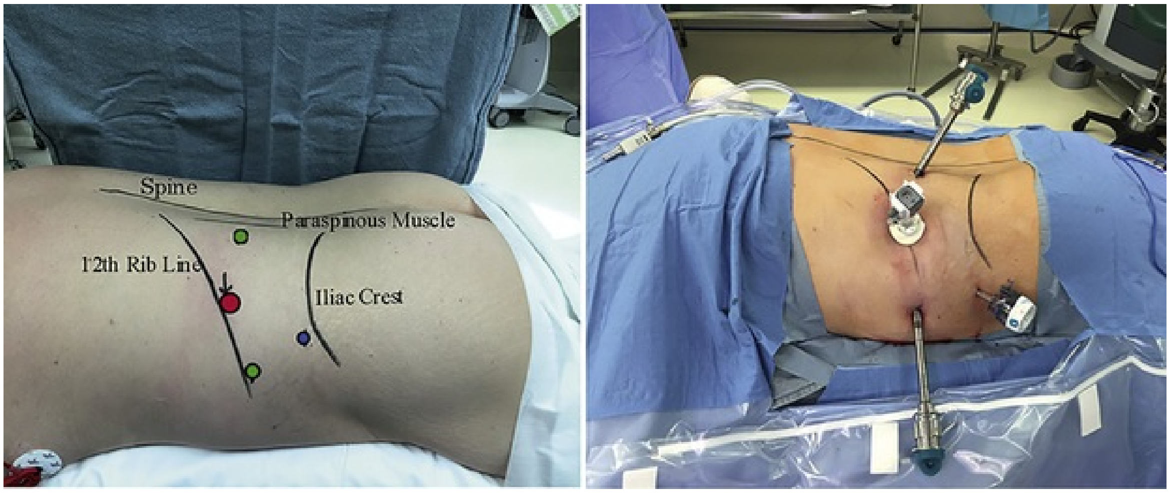

FIG. 107.36 Robot-assisted posterior retroperitoneal adrenalectomy. ● Camera port; ● 8-mm robotic ports; ● assistant port. (From Feng Z, Feng MP, Levine JW, et al.: Robotic retroperitoneoscopic adrenalectomy: useful modifications of the described posterior approach. *J Robot Surg* 11(4):409–414, 2017.)

With the 30-degree camera looking down, dissection began from lateral to medial, detaching the tissue above the kidney. A laparoscopic ultrasound can be used to help localize the adrenal gland. The kidney was retracted caudally by the assistant. The adrenal gland was mobilized from the superior aspect of the kidney, and the adrenal vein could be identified and clipped. Dissection of the adrenal gland can be complete by mobilizing it from the retroperitoneal attachments and removing it and placing it into a specimen bag.

Hand-Assisted Surgery

Hand assistance during laparoscopic surgery introduces enhanced tactile sensation and greater degrees of freedom of movement as compared with laparoscopic instruments. This may result in easier dissection, added security in the event of bleeding complications, and a shorter learning curve. With the introduction of the robotic system, hand-assisted adrenalectomy may have fallen out of favor in recent years, with publications limited to case reports and small case series published in the early 2000s. Hand-assisted adrenalectomy may be indicated in bilateral adrenalectomy or with large adrenal tumors that may require a larger incision for extraction. **There may also be a role for hand-assisted surgery as an alternative to open conversion should laparoscopic dissection prove difficult or for bleeding complications.**

Laparoendoscopic Single-Site Adrenalectomy

LESS surgery has recently been developed based on the principle that, with a smaller number of incisions and ports, enhancement of cosmesis and reduction of associated port site complications such as bleeding, organ injury, and incisional hernias can be attained. In general, all patients eligible for laparoscopic adrenalectomy can be considered for LESS depending on the surgeon's experience. However, because of the technical difficulties, LESS is most commonly performed for small (≤4 cm) and benign tumors.

Like conventional laparoscopic adrenalectomy, transperitoneal and retroperitoneal approaches for LESS adrenalectomy have been described. Single multiluminal access ports are commercially available for LESS access. The umbilicus is the most common location for LESS access because of the superior cosmetic results. However, the longer distance and the more tangential approach from the umbilicus to the adrenal gland render the surgery much more challenging. Alternative sites such as the subcostal margin or retroperitoneum have been described, albeit with less cosmetically appealing results. Moreover, the limited working space in the retroperitoneum makes the use of articulating and curved instruments more difficult when compared with the transperitoneal approach.

The inherent disadvantages of LESS surgery include reduced working space and loss of instrument triangulation leading to clashing, crossover, and paradoxic movement of instruments, as well as suboptimal approach to the adrenal gland and inadequate traction and countertraction. These disadvantages may translate into longer operative time and increased risk of tissue injuries and complications, especially during the early learning curve. Jeong et al. (2009) reported the first matched case-control study comparing 9 patients who underwent LESS adrenalectomy with 17 patients who underwent conventional laparoscopic adrenalectomy. Although the LESS adrenalectomy group required reduced postoperative analgesia, it was associated with a non–statistically significant longer operative time and a case of bowel injury. Similarly, Shi et al. (2011) and Walz et al. (2010) reported a longer median operative time and lower analgesic requirements after LESS adrenalectomy compared with conventional adrenalectomy. Ishida et al. (2013) showed that tissue regrasping was more frequently observed (16.2 vs. 2.2 times) during LESS than in conventional adrenalectomy. Hu et al. (2013) summarized in their meta-analysis comparing earlier studies of LESS adrenalectomy and conventional laparoscopic adrenalectomy that, although LESS adrenalectomy is associated with a longer operative time, estimated blood loss and complications are similar. In addition, patients who underwent LESS adrenalectomy had a shorter hospital stay and reduced requirement for analgesia.

The learning curve leading to a decrease in operative time for LESS adrenalectomy has been estimated by Fukumoto et al. (2017) to be about 30 cases. Many recent studies had reported no significant difference in operative time when comparing LESS adrenalectomy and conventional laparoscopic adrenalectomy. Indeed, a recent meta-analysis of 704 cases by Wu et al. (2016) reported that LESS adrenalectomy was associated with shorter length of hospital stay and lower postoperative pain scores with no significant difference in operative time, estimated blood loss, resumption of oral intake, dose of analgesic required, perioperative complications, conversion, transfusion, or pain medications required compared with conventional laparoscopic adrenalectomy.

Natural Orifice Transluminal Endoscopic Surgery–Assisted Laparoscopic Adrenalectomy

NOTES uses natural orifices such as the mouth, urethra, vagina, or anus as entry points to perform intra-abdominal surgeries. In pure NOTES, access points are strictly limited to natural orifices. Hybrid-NOTES allows for additional incisions to be made, usually around the umbilicus, to facilitate surgery. Like LESS, the aims of NOTES are to improve cosmetic outcomes and convalescence and reduce hospitalization stay and analgesia requirements without compromising safety and efficacy.

Fritscher-Ravens et al. (2008) were among the first to attempt NOTES adrenalectomy. By using the transesophageal or transgastric route with the aid of endoscopic ultrasonography, they failed to remove the adrenal gland in all procedures in which it was attempted. Perretta et al. (2009) successfully performed bilateral adrenalectomy in two female pigs and two female cadavers through a transvaginal retroperitoneal approach. The first report of hybrid-NOTES came from Zou et al. (2011), who presented their series of 11 female patients, with a median tumor size of 4.7 cm, who underwent transvaginal NOTES adrenalectomy. Injury to the spleen occurred in one patient, necessitating open conversion and splenectomy. Median estimated blood loss was 80 mL. Almost all published literature describes NOTES adrenalectomy via the transvaginal route. Eyraud et al. (2013) described their transrectal robot-assisted NOTES techniques in a male cadaver. The paucity of publications of NOTES adrenalectomy in the recent years may indicate a decline in interest in this approach. Currently, NOTES adrenalectomy is still in its infancy and should only be considered experimental.

Partial Adrenalectomy

Unilateral adrenalectomy is often well tolerated and should be considered as the gold standard in the treatment of functioning or malignant adrenal tumors. Patients with bilateral adrenalectomy require lifelong adrenal replacement therapy. Unfortunately, fixed daily dosing of steroids is associated with overdosing, which may result in osteoporosis, obesity, and Cushing syndrome, and with underdosing in times of stress. Life-threatening Addisonian crisis can occur. Patients after bilateral adrenalectomy continue to report poorer quality of life as compared with the general population (Hawn et al., 2002; van Aken et al., 2005): 30% reported constant tiredness with severe activity limitations; 48% of patients consider themselves to be handicapped (Debono M et al., 2009). Therefore partial adrenalectomy should be considered in patients with bilateral adrenal tumors, solitary adrenal gland, or familial syndromes such as von Hippel-Lindau disease, familial pheochromocytoma, and multiple endocrine neoplasia type IIA. Indications for partial adrenalectomy are summarized in Box 107.5. A review of 417 patients undergoing partial adrenalectomy published in 2010 by Kaye et al. found that the procedure was associated with minimal morbidity, a 3% recurrence rate, and the freedom from steroid replacement in 90% of patients.

Box 107.5

Indications for Partial Adrenalectomy

- Bilateral hereditary pheochromocytoma
  - Endocrine syndromes MEN I and II
  - von Hippel-Lindau syndrome
  - Neurofibromatosis type 1
  - Hereditary pheochromocytoma-paraganglioma syndrome (PGL)
  - Unilateral pheochromocytoma in documented genetic cases
- Primary aldosteronism resulting from unilateral adrenal adenoma with the opposite normal adrenal gland
- Unilateral adrenal adenoma in Cushing syndrome
- Pseudocyst or adrenal endothelial cyst

Partial adrenalectomy can be performed in any of the open, laparoscopic, or robot-assisted approaches described earlier. **A major and important difference is that the adrenal gland is exposed but not mobilized to preserve the arterial and venous blood supply, especially in cases in which the main adrenal vein has to be sacrificed.**

Accurate localization of the adrenal tumor in question is paramount for a successful partial adrenalectomy. In open surgery, the tumor can usually be visualized or palpated. In laparoscopic or robotic surgery, lesions larger than 1 cm can usually be visualized. In any of these approaches, the use of intraoperative ultrasonography can help accurately localize and identify the tumor. More recently, Manny et al. (2013) demonstrated use of fluorescent dye indocyanine green (ICG, IC-Green; Akorn Pharmaceuticals, Lake Forest, IL) during robotic surgery for better visualization of three different adrenal tumors (one pheochromocytoma, one lipoadenoma, and one benign nodular hyperplasia). Two milliliters of a 2.5 mg/mL solution were administered intravenously, and the robot (Intuitive Surgical, Sunnyvale, CA) was toggled to near-infrared (NIR) fluorescent mode. The adrenal parenchyma was seen to become fluorescent at an intensity only slightly less than the adjacent kidney but significantly less than the liver, while all three adrenal tumors were identified as hypofluorescent masses.

Once the lesion is identified, only the affected portion is mobilized. The arterial supply of the adrenal gland forms a plexus circumferentially around the gland and can usually be removed without fear of devascularizing the adrenal cortex. The gland will remain viable as long as it remains attached to the kidney or to an area of unmobilized connective tissue. The venous system drains into a central adrenal vein. Opinions are divided as to whether the main adrenal vein should be left intact during partial adrenalectomy. Some authors believe that removing the main adrenal vein will result in congested remnant adrenal tissues and difficult hemostasis, thus advocating its preservation (Imai et al., 1999; Janetschek et al., 1998). In our experience and as other authors concur, the main adrenal vein can be removed as long as the remnant adrenal gland remains in situ without mobilization (Kaouk et al., 2002; Walz et al., 1998). However, it would be prudent to preserve the main adrenal vein as long as it is safe and adequate margins can be obtained.

Partial adrenalectomy can be performed with either an endoscopic stapler (Imai et al., 1999), a harmonic scalpel (Sasagawa et al., 2000; Walz et al., 1998), or cautery or cold endoscissors with clips or suture ligation. The use of the endoscissors allows for clear identification of the tumor plane and precise dissection but may lead to more bleeding. Finally, the cut surface can be sealed with fibrin glue or Surgicel (Ethicon, Cincinnati, OH) to prevent delayed bleeding. Frozen section is recommended if available; if not, intraoperative ultrasonography can be performed to confirm gross complete resection.

The amount of adrenal tissue that must be left behind after partial adrenalectomy to avoid insufficiency is not known. It has been suggested previously that at least 20% of the adrenal gland should be preserved (Lee et al., 1996). However, Lee et al. were unable to correlate the amount of adrenal tissue preserved with the presence of adrenal insufficiency. More recent studies seem to suggest at least a third of the adrenal gland should be preserved (Brauckhoff M et al., 2003, 2008). Excision of tumor with a 3- to 5-mm margin is recommended.

Outcomes

Open Versus Laparoscopic Adrenalectomy

There has been only one randomized controlled trial comparing open with laparoscopic adrenalectomy. This was a small study consisting of 22 patients with pheochromocytoma, and the authors concluded that although laparoscopic adrenalectomy was associated with lower blood loss, shorter operative time and shorter hospital stay, there was an insignificant trend toward higher hemodynamic instability intraoperatively (Tiberio et al., 2008). It is highly doubtful that a large randomized controlled trial will ever be conducted because laparoscopic adrenalectomy is emerging as the gold standard technique for benign lesions, and surgeons are pushing the boundaries for laparoscopic management of malignant tumors. A cohort analysis performed using the Nationwide Inpatient Sample between 2002 and 2011 showed that of the nearly 60,000 adrenalectomies performed in the United States, 20% were performed with the minimally invasive approach with a 4% increase in the minimally invasive approach over the study period (Monn et al., 2015). Many large retrospective studies have consistently demonstrated superior outcomes of laparoscopic adrenalectomy over open surgery in terms of analgesia, hospital stay, blood loss, and complication rates. As surgeons gain more experience with laparoscopic surgeries, operative times have also decreased tremendously.

In an early meta-analysis of close to 100 studies comparing laparoscopic with open adrenalectomy, Brunt (2002) reported that, although the rate of bleeding complications was higher in laparoscopic (4.7%) than open (3.7%) adrenalectomy, total complication rates were lower in laparoscopic (10.9%) than open (25.2%) adrenalectomy. Open adrenalectomy was associated with significantly higher rates of associated organ injury and wound, pulmonary, cardiac, and infectious complications. There was also a higher non–statistically significant rate of mortality after open adrenalectomy (0.9% vs. 0.3%). Using the Veterans Affairs National Surgical Quality Improvement Program database to compare laparoscopic with open adrenalectomy, Lee et al. (2008) demonstrated that open procedures had increased operative times, transfusion requirements, reoperations, length of stay, and 30-day morbidity rates. Open adrenalectomy had also resulted in more pneumonia, unplanned intubation, unsuccessful ventilator wean, systemic sepsis, cardiac arrest, renal insufficiency, and wound infections. The 30-day morbidity rate was still higher even after adjusting for confounding factors.

Most recently, using a contemporary cohort from the American College of Surgeons National Surgical Quality Improvement Program (ACS-NSQIP) data, Elfenbein et al. (2013) concluded that patients undergoing laparoscopic adrenalectomy had significantly lower postoperative morbidity and shorter length of stay than patients undergoing an open procedure after adjustment for patient- and procedure-related factors, including malignancy. Similarly, a recent Nationwide Inpatient Sample from the United States involving close to 60,000 patients who underwent adrenalectomy echoed similar findings of fewer complications (8% vs. 13%) and shorter length of stay (2 days shorter) in patients who underwent laparoscopic adrenalectomy over their open adrenalectomy counterparts (Monn et al., 2015).

A recent network meta-analysis evaluation of open and minimally invasive adrenalectomy (Heger et al., 2017) yielded some interesting findings. In terms of complication rates, there was a significantly higher complication rate after open adrenalectomy than after laparoscopic surgery. The robotic approach was considered to have the lowest postoperative complication rate. Operating time was significantly shorter for open surgery than the retroperitoneoscopic and laparoscopic approaches, whereas intraoperative blood loss was significantly higher with open than with laparoscopic surgery with robotic approach resulting in the least blood loss. Finally, minimally invasive approaches were associated with a significantly shorter hospital stay than open surgery with the retroperitoneoscopic approach demonstrating the shortest length of hospital stay.

Laparoscopic Transperitoneal Versus Retroperitoneal Approach

Multiple retrospective studies have been performed that seem to suggest an advantage in terms of lesser blood loss and shorter convalescence time of the retroperitoneal approach over the transperitoneal approach. In a meta-analysis of 22 eligible studies (Constantinides et al., 2012), the laparoscopic retroperitoneal approach was associated with a significantly shorter hospital stay when compared with the transperitoneal approach. The authors attributed this to the decrease in postoperative pain and ileus associated with the retroperitoneal approach because the peritoneum is not breached. There were no differences in duration of operation, blood loss, time to ambulation and oral intake or complication rates between techniques. Another meta-analysis by Chen et al. (2013) identified nine eligible retrospective studies reporting that the retroperitoneal approach was associated with shorter operative time, less intraoperative blood loss, shorter hospital stay, and shorter time to first ambulation. There was no significant difference in open conversion rates, time to first oral intake, and major postoperative complication rates.

Three randomized prospective studies were carried out to compare these two approaches. Fernández-Cruz et al. (1996) randomized 21 laparoscopic adrenalectomy patients into transperitoneal and retroperitoneal approaches. They showed that the transperitoneal approach resulted in a greater rise in the $\mathrm{Pa}_{\mathrm{CO}_2}$ level compared with the retroperitoneal approach at 30 minutes, together with a significant increase in mean arterial pressure. However, operation time, blood transfusion and analgesia requirements, hospital stay, return to normal activities, and complication rates were similar between the two approaches. The authors concluded that the retroperitoneal approach may be a better option in patients with previous abdominal surgery and preexisting cardiopulmonary diseases. In another prospective randomized trial by Rubinstein et al. (2005) in which all baseline patient and operative factors were matched, the only significant difference was a shorter convalescence time in the retroperitoneal group. All other parameters such as blood loss, operative time, analgesia requirements, open conversion, and complication rates were similar. Finally, a prospective randomized study involving a more contemporary cohort concurred with the previous findings that the transperitoneal approach was comparable to the retroperitoneal approach in terms of operative time, estimated blood loss, time to ambulation, hospital stay, and analgesic requirement but was associated with longer time to oral intake resumption and longer convalescence period (Mohammadi-Fallah et al., 2013).

Ball et al. (2017) recently compiled an evidence-based systematic review on the use of minimally invasive adrenalectomy as part of the International Consultation on Urological Diseases (ICUD) and European Association of Urology (EAU) consultation. They concluded that transperitoneal and retroperitoneal approaches are equally effective, and one or the other should be chosen based on surgeon training and experience (Grade A).

Laparoscopic Versus Robot-Assisted Adrenalectomy

As described previously, the robotic platform offers several advantages over conventional laparoscopy, but current literature has yet to show conclusively that these advantages have translated into better clinical outcomes. A prospective randomized study comparing robot-assisted with laparoscopic adrenalectomy was published in the early years of robot-assisted surgeries. Morino et al. (2004) randomized 20 consecutive patients with benign adrenal tumors to either traditional laparoscopic or robotic surgery. The robot-assisted approach was associated with a longer operative time and higher 30-day complication rate compared with the laparoscopic approach. In addition, cost analyses revealed that robotic procedures were more expensive than laparoscopic procedures. The authors concluded that laparoscopic adrenalectomy was superior to robot-assisted adrenalectomy in terms of feasibility, morbidity, and cost. In separate studies, Brunaud et al. concurred that patients' quality of life after robotic surgery was similar to that after laparoscopic surgery (Brunaud et al., 2004), but robotic surgery was 2.3 times more expensive (Brunaud et al., 2008). However, this increase in cost can be mitigated in high-volume centers. Probst et al. (2016), in a recent paper comparing costs of robotic adrenalectomy and open adrenalectomy, demonstrated that the additional costs of robotic surgery were equalized if at least 150 cases of robotic procedures were performed per year based on certain health care cost assumptions within the health care system.

Robot-assisted surgery requires the insertion of more trocars and docking of the robotic arms when compared with conventional laparoscopy, and these additional steps may lead to longer operative time (Morino et al., 2004; Pineda-Solís et al., 2013; Wu et al., 2008). Robotic surgery is highly dependent on the expertise of the assistant and the whole robotic team, including the scrub nurses. As robotic teams go beyond the initial learning curve of 10 to 20 cases, operative times have been shown to approach those clocked by the conventional laparoscopic approach (Agcaoglu et al., 2012a; Brunaud et al., 2008; Karabulut et al., 2012). Karabulut et al. (2012) went further to time each individual step of adrenalectomy and reported similar timings for each step of robotic and laparoscopic adrenalectomy, except for shorter hemostasis time in the robotic group.

Multiple studies have demonstrated that perioperative outcomes such as estimated blood loss, hospital stay, postoperative analgesia, and complication and mortality rates are similar between the two approaches. In fact, robot-assisted adrenalectomy may be preferred in certain circumstances. For tumors greater than 5 cm, Agcaoglu et al. (2012b) reported shorter operative time and hospital stay and lower open conversion and morbidity rates in robot-assisted as compared with conventional laparoscopy. In a separate study by Karabulut et al. (2012), the morbidity was 10% in the laparoscopic and 2% in the robotic group despite the fact that tumors in the robotic group were significantly larger. For obese patients with body mass index 30 kg/m^2 or greater, Aksoy et al. (2013) found no differences in operative time, estimated blood loss, and hospital stay between robot-assisted and laparoscopic adrenalectomy. However, there was a lower conversion rate (0 vs. 5.2%) and a non–statistically significant lower 30-day morbidity rate (4.8% vs. 7%, $P = 0.06$) in favor of the robotic approach (Aksoy et al., 2013). Society of Gastrointestinal and Endoscopic Surgeons (SAGES) 2013 guidelines suggested that the use of robot-assisted adrenalectomy in patients with a high BMI as well those with larger tumors may be advantageous.

Being early in a surgeon's learning curve is associated with worse perioperative outcomes and increased complications. It has been estimated that the learning curve of laparoscopic adrenalectomy is between 20 and 40 cases, whereas that of robot-assisted transperitoneal adrenalectomy is only about half, ranging between 10 and 20 cases. Data for robot-assisted adrenalectomy are maturing in recent years as surgeons gain more experience in this approach. Three recent meta-analyses showed some benefits of robotic approach over the standard laparoscopic approach. In an analysis of nine studies (600 patients), Brandao et al. (2014) reported a shorter hospital stay, less blood loss, and lower occurrence of postoperative complications in patients who underwent robot-assisted adrenalectomy when compared with standard laparoscopic adrenalectomy. Tang et al. (2015) analyzed eight trials and showed that, although the robotic approach was associated with a longer operative time, it was associated with significantly less blood loss and shorter hospital stay over standard laparoscopy. Finally in the largest meta-analysis comprising 27 trials and 1162 patients (Economopoulos et al., 2017), it was demonstrated that there was no significant difference between the robotic and the laparoscopic groups for intraoperative complications, postoperative complications, mortality, conversion to laparotomy or laparoscopy, blood loss, and operative time. The only significant difference found was a shorter hospital stay in favor of robot-assisted adrenalectomy.

Complications

Intraoperative

Box 107.6 summarizes the intraoperative complications that can occur. As expected, adrenal surgery, both open and laparoscopic, can involve injury to adjacent organs. Hemorrhage is a potentially catastrophic complication of adrenal surgery. Bleeding can result from injury to the adrenal vein, inferior vena cava, lumbar vein, or renal vein. These injuries are managed initially by application of direct pressure to the injury. Grasping a small injury with an Allis clamp (Scanlan International, St. Paul, MN) and closing it with suture or by placement of a vascular clamp for a larger vena cava injury may be curative. In the early days of laparoscopic adrenalectomy, open conversion was the typical consequence of vascular injury. However, with increasing experience with laparoscopic suturing techniques, these injuries are often managed as in the open surgery.

Box 107.6

Intraoperative Complications of Adrenal Surgery

Access Related

Abdominal wall hemorrhage
Cutaneous nerve injury
Visceral injury by Veress needle or trocar

Hemorrhage

Inferior vena cava or aorta
Adrenal vein
Lumbar vein
Hepatic vein
Remnant adrenal gland after partial adrenalectomy

Ischemia

Ligation of renal artery or vein
Ligation of superior mesenteric artery and vein

Injury to Neighboring Organs as a Result of Thermal Energy or Incorrect Plane of Dissection

Lung—pneumothorax
Pancreas
Liver
Spleen
Stomach and bowel, especially duodenum
Kidney

Hemodynamic Instability

Pheochromocytoma

Modified from Vaughn ED: Complications of adrenal surgery. In Taneja SS, Smith RB, Ehrlich RM, editors: *Complications of urologic surgery: prevention and management*, ed 3, Philadelphia, 2001, p 366.

Ischemic injuries can occur as well. An upper pole renal artery branch can be divided inadvertently during dissection. If the branch is small and supplies a minimal portion of the kidney, it can be ignored. More substantial injuries may require a revascularization attempt. If the patient has a large tumor, there can be distortion of the regional anatomy, and inadvertent ligation of the superior mesenteric vein or artery is possible. This is a potentially fatal injury, and one must have a high index of suspicion to restore vascular supply to the bowel as soon as possible.

The adjacent organs can be injured during dissection of the adrenal gland. The liver can be injured during right adrenalectomy. Liver lacerations can be treated with argon beam coagulation and application of hemostatic agents such as methylcellulose. More serious injuries may require hemostatic sutures with a blunt-tip liver needle. The spleen can be injured during left adrenalectomy. As with hepatic injury, argon beam coagulation and hemostatic agents can be used to control bleeding. If this is not sufficient, splenorrhaphy can be attempted. If these measures are unsuccessful, splenectomy may be necessary. **It is important**

to remember to give pneumococcus, *Haemophilus influenzae* type B (Hib) and meningococcus vaccinations to these patients during postoperative care.

The pancreas can be injured during surgery on either the right or left adrenal gland. If an injury to the tail of the pancreas occurs, distal pancreatectomy may be performed. If the injury is to the pancreatic duct, this may be repaired and surgical drains left. If there is uncertainty of pancreatic injury, leaving closed-suction surgical drains behind is advisable. Postoperative drainage high in triglycerides is indicative of pancreas injury. Management consists of bowel rest with parenteral nutrition. The administration of octreotide can decrease pancreatic secretions while the pancreas heals.

The proximity of the kidney to the adrenal gland can be a problem in cases of large adrenal cortical carcinomas. **It is imperative for all patients undergoing surgery for large adrenal masses to be counseled about the possibility of concurrent en bloc nephrectomy.**

During 11th-rib or higher flank adrenalectomy, it is not unusual for pleural injury to be incurred. These injuries can be repaired with a purse-string chromic suture and a red rubber catheter to water seal. Expulsion of air from the pleura followed by cinching of the purse-string suture usually repairs the defect. Postoperative chest radiography should be routinely performed after flank or thoracoabdominal nephrectomy. If a significant pneumothorax is present, a chest tube should be placed.

With pheochromocytoma, blood pressure fluctuations can be life threatening. The anesthesiologist typically manages high blood pressure with short-acting β-blockade, alpha-blockers, or nitroprusside. Arrhythmias are usually treated with beta-blockers. When the adrenal vein is ligated, there can be a sudden drop in blood pressure. It is important to inform the anesthesiologist just before the adrenal vein is ligated to avoid any nasty surprises. Fluid repletion and vasopressors may be necessary to bring the pressure to normal.

With the emergence of minimally invasive surgery, access-related complications can occur. Bleeding from the abdominal wall can occur after trocar insertion. Care should be exercised to avoid visible superficial veins during trocar site insertion. Although bleeding usually stops from the tamponade effect of the trocar and pneumoperitoneum, it is imperative to inspect all trocar sites laparoscopically upon trocar withdrawal at end of surgery to ensure hemostasis. Cutaneous nerve injury is less likely to occur than in open surgery because of smaller incisions. Finally, visceral injury by the Veress needle can occur. Closed access technique using the Veress needle must be done with caution in patients with previous abdominal surgery because bowels may be adherent to the abdominal wall and can be injured. The open (Hasson) access technique can be a safer alternative in these cases.

Postoperative

The American College of Surgeons National Surgical Quality Improvement Program reported a 7.5% overall complication rate in 4844 patients who underwent adrenalectomy during the period of 2005 to 2012 (Sood et al., 2016). Of these, 43.2% occurred postdischarge. The overall blood transfusion, reintervention, readmission, and mortality rates were 3.9%, 2.0%, 6.4%, and 0.6%, respectively. The median time to major complications was 4 days, whereas for minor complications it was 9 days from surgery; most complications occurred within the first 2 weeks postadrenalectomy (Sood et al., 2016). A previous nationwide study by Park et al. using the Nationwide Inpatient Sample (NIS) reported an overall inpatient complication rate of 16% between 1999 and 2005. This improvement in overall complication rate is likely due to increased experience in adrenalectomies.

Box 107.7 summarizes the postoperative complications that can occur. Disease-specific complications must be accounted for to ensure an uneventful postoperative course. Risk factors associated with increased complication rates include larger tumor sizes, functional adrenocortical adenocarcinoma or adenoma, and conversion to open surgery (Thompson et al., 2017).

Box 107.7

Postoperative Complications of Adrenal Surgery

Primary Aldosteronism

Hypokalemia: secondary to continued potassium loss immediately postoperative

Hyperkalemia: secondary to failure of contralateral adrenal to secrete aldosterone

Cushing Syndrome

Inadequate steroid replacement leading to hypocorticism
Fracture secondary to osteoporosis
Hyperglycemia
Poor wound healing
Increased risk of infections

Pheochromocytoma

Hypotension secondary to α-adrenergic blockade after tumor removal

Generic Complications

Hemorrhage
Pneumothorax
Pancreatitis
Pneumonia
Prolonged ileus
Intra-abdominal collections

Modified from Vaughn ED: Complications of adrenal surgery. In Taneja SS, Smith RB, Ehrlich RM, editors: *Complications of urologic surgery: prevention and management*, ed 3, Philadelphia, 2001, Saunders, p 368.

Patients with primary hyperaldosteronism require close monitoring of potassium levels because they can be either hypokalemic or hyperkalemic. Hyperkalemia, secondary to contralateral adrenal zona glomerulosa suppression, should be managed medically with the typical hyperkalemia regimens. Hypokalemia can persist in the immediate period after adrenalectomy, and this should be corrected with potassium repletion. In patients who had only one adrenal gland to begin with, mineralocorticoid replacement with fludrocortisone is essential.

Patients with Cushing syndrome require steroid replacement after surgery until the contralateral gland recovers function. Measurements of plasma cortisol can be useful in determining when steroid replacement can be tapered. Furthermore, these patients have increased risk of fracture secondary to osteoporosis, hyperglycemia, and poor wound healing.

Patients with pheochromocytoma may have hypotension secondary to α-blockade. These patients need to be monitored closely until α-blockade wears off, often in the intensive care unit. If α-blockade was not used preoperatively, intensive care stay is unnecessary in most cases.

Ablative Therapy for Adrenal Tumors

Ablative therapies can be performed either percutaneously with imaging guidance or intraoperatively, usually laparoscopically. Current indications for ablative therapy for adrenal tumors include patients with small hyperfunctional tumors not keen on or suitable for surgery, treatment of oligometastatic lesions or palliation of metastases not amenable to resection. In such cases, the size of the lesion is an important factor to achieving complete tumor ablation. The smaller the size of the lesion, the greater the likelihood of complete treatment. Although the threshold size to expect therapeutic response has not been well evaluated, better results have been reported for adrenal tumors measuring 5 cm or smaller (Wood et al., 2003). In addition, patients with normal-appearing adrenal glands or with multiple nodules are not candidates for ablation because of the uncertainty of location of the hyperfunctioning nodule. Proximity of the nodule to the inferior vena cava may cause a heat sink effect, reducing the efficacy of the ablation.

The three major thermal ablative techniques currently used are radiofrequency ablation (RFA), cryoablation, and microwave ablation. RFA uses frictional energy created by oscillating tissue ions to supply destructive heat to target tissue, with target tissue temperature ranging from 60°C to 100°C, resulting in protein and enzymatic degradation and cell death. The advantages of RFA include a well-established safety profile, widespread availability, and predictable thermal volumes based on the probe type. Microwave ablation creates an alternating electric field that causes oscillation of surrounding water dipoles resulting in tissue heating. Some authors have suggested that advantages of microwave ablation include the ability to achieve higher local temperatures, the potential for larger ablation volumes in a shorter ablation time, decreased procedural pain, and the potential to treat cystic lesions (Simon et al., 2005). Cryoablation relies on rapid freezing and thawing to cause rupture of cell membranes resulting in cell death. The main advantage of this technique is the ability to follow iceball formation in real time with CT imaging, reducing the risk of injury to surrounding organs. The main limitations of cryoablation are the increased risk of hemorrhage caused by microvascular thrombosis and the inability to coagulate tissue during probe withdrawal such as can be done with RFA and microwave ablation, leading to a theoretical risk of tract seeding.

Planning the route of approach is very important to ensure complete ablation of the lesion and avoiding complications. The main complications are injury to neighboring organs such as the liver, spleen, bowels, or lungs and hemorrhage. To reduce the risk of hemorrhage, it is important to identify and consider any critical vascular structures that lie adjacent to the adrenal glands, including the inferior vena cava, aorta, renal arteries, and lumbar collateral vessels. If the lesions are hypervascular, such as metastases from hepatocellular carcinoma or renal cell carcinoma, combination therapy with adrenal arterial embolization and ablation therapy can be useful for preventing hemorrhagic complication and reinforcing antitumoral effects.

It is generally recommended to perform a biopsy of the tumor either before or at the same session as ablative therapy because histologic results may influence follow-up management. Systemic catecholamine release resulting in hypertensive crisis and cardiac arrest has been reported during ablative treatment of adrenal metastases, hyperfunctioning tumors, and pheochromocytomas (Chini et al., 2004; Mamlouk et al., 2009; Tsoumakidou et al., 2010). **Because catecholamine release can be caused by thermal injury to the adrenal in the absence of pheochromocytoma,** some authors advocate premedication with α-blockade before the ablation procedure. Welch et al. (2011) demonstrated a significant increase in systolic blood pressure, pulse pressure, and mean arterial pressures in patients undergoing adrenal cryoablation, even with prior α-blockade. Continuous blood pressure monitoring with an arterial line and general anesthesia with a rapid-acting vasodilatory drug on standby may be prudent.

Ablative therapy is most commonly performed for hyperfunctioning tumors. Mendiratta-Lala et al. (2011) treated 13 hyperfunctioning small adrenal tumors with RFA. At a mean follow-up of about 21 months, all patients experienced resolution of clinical symptoms or syndrome and normalization of biochemical markers. The majority of current literature on ablative therapy is centered on treatment of metastases in the adrenal gland. The largest of these studies by Wolf et al. (2012) reported that 19 of 23 tumors treated showed no evidence of local progression and tumor enhancement at mean follow-up of 45.1 months after RFA or microwave ablation. Other studies also mirrored excellent short-term local progression-free and enhancement-free rates ranging from 83% to 100% after RFA, microwave ablation, or cryoablation (Carrafiello et al., 2008; Mayo-Smith and Dupuy, 2004; Wang et al., 2009; Welch et al., 2011). When compared with laparoscopic adrenalectomy, no prospective randomized trial is available. Studies by Sarwar et al. (2016) and Yang et al. (2016) showed no statistically significant difference in treatment results when comparing ablation with adrenalectomy. However, Liu et al. showed lower rates of hypertension resolution with radiofrequency ablation compared with laparoscopic adrenalectomy (92% vs. 100%). Nonetheless, when compared with surgery in all three studies, radiofrequency ablation had a number of significant advantages including shorter operative time, shorter hospital stay, less analgesic requirements, less blood loss, lower complication rates, and earlier resumption of work. Evidence of long-term follow-up and outcomes are generally lacking. Liu et al. reported at long-term follow-up of about 6 years after RFA of aldosterone-producing adenoma, treatment success was maintained in 92% of patients, all of whom had biochemical markers in the normal range with a 0 recurrence rate.

In the treatment of malignant tumors, ablative therapy is more commonly used in the management of metastatic lesions than primary adrenocortical carcinomas. Using thermal ablation, the reported rates of residual or recurrent disease in treating adrenal malignancies are as low as 0 to 25%, with a mean follow-up of 10.3 to 37.7 months (Li et al., 2011; Welch et al., 2011; Wolf et al., 2012; Wood et al., 2003).

Future of Adrenal Surgery

Although the adrenal glands or adrenal tumors can usually be identified fairly easily intraoperatively in most cases, there are certain situations in which accurate localization of the gland or tumor is more difficult: for example, in patients with severe obesity, previous abdominal surgeries with dense intra-abdominal adhesions or small adrenal tumors in which partial adrenalectomy is to be attempted. The most widely used adjunct for this purpose currently is the intraoperative laparoscopic ultrasound and is associated with some limitations such as poor visualization at certain difficult angles, contributed partly by the fairly bulky probe and the limitations of degree of movement of the probe. Recently, the use of ICG and radionuclide isotopes such as ^{131}I-iodocholesterol with gamma probe had been tried in a few patients with encouraging success. DeLong et al. (2015) showed that with the help of ICG and near-infrared (NIR) fluorescence, they were able to perform four cases of laparoscopic adrenalectomy with lesser blood losses and shorter operative times. Sound et al. (2016) reported differentiated uptake of ICG under NIR depending on the adrenal pathologies. They found that primary hyperaldosteronism was associated with increased uptake of ICG, whereas adrenocortical carcinoma and pheochromocytoma were associated with little or no ICG uptake. These findings are potentially helpful in tumor localization especially during partial adrenalectomies. One limitation of ICG is for right adrenalectomies, the liver will have similar uptake with the adrenal gland, and this may potentially lead to difficulties in the identification of the right adrenal gland.

Contemporary computer-based image acquisition systems are able to perform accurate 3D reconstruction of an organ or body region. Surgeons are now able to manipulate these 3D images so that the organ or body region could be viewed from almost all angles, allowing surgeons to acquire a mental picture of the regional anatomy they will be dealing with before surgery. 3D printing technologies currently allow surgeons to have an exact, individualized replica of the adrenal gland to aid surgery (Srougi et al., 2016) Currently, virtual reality systems are being developed that will allow for the creation of a virtual environment in which organs and structures can be represented in a fully 3D manner and surgeons can interact with the images as though they truly exist and perform tasks and surgical manipulations (Marescaux et al., 2005). In addition, the differentiation between the structure of the normal gland and pathological lesions can be enhanced with high contrast and color, allowing for accurate localization of pathological lesions and their relationship with the surrounding structures.

There are a few potential clinical applications for these virtual reality systems (Marescaux et al., 2005). First, by integrating with surgical simulators, residents and junior surgeons are able to gain surgical experience in a completely safe environment where errors could be made without detrimental consequences to the patient. Second, the integrated system can allow the surgeon to have an individualized “dry run” of a patient's surgery before the actual procedure, allowing for better planning as well as anticipation of possible dangers and identification of the optimal plane for dissection or resection. Third, there are currently applications in initial clinical trials that allow 3D reconstruction images of an organ to be superimposed as an overlay onto the target organ on the operating field via the tile-pro technology of the da Vinci Surgical Robotic Platform, allowing surgeons to see in real time the surrounding vasculatures as well as the tumor during the surgery. This is especially helpful in partial adrenalectomies or in cases of complex adrenal or renal vasculatures. Finally, by integrating these virtual reality systems with advanced surgical robots in future, the digital data of the best simulated procedure performed by an expert could be recorded and transmitted to a distant remote location where a robot reproduces the surgery automatically on a patient. In fact, the first clinical application has already been developed by Kurenov et al. (2017). The system included a surgeon-authored virtual reality (VR) training module authored by surgeons using the Toolkit for Illustration of Procedures in Surgery (TIPS) and two 6 degrees of freedom haptic devices simulating laparoscopic instruments providing physical feedback to the training surgeon.

The future of adrenal surgery remains exciting and fascinating. Science fiction of today may become the reality of tomorrow.

Key Points: Surgery of the Adrenal Glands

- Adrenalectomy is indicated in functional adrenal masses or suspected adrenal malignancy, either primary adrenal cortical carcinoma or solitary metastasis from nonadrenal sources.
- Preoperative and postoperative medical management is essential for optimal surgical outcome for functional adrenal tumors.

- Laparoscopic adrenalectomy is the current standard of care for adrenal lesions with the exception of invasive adrenal cortical carcinoma or adrenal cortical carcinoma with caval thrombus. Robot-assisted adrenalectomy is emerging as an alternative approach especially in more complex cases such as obese patients or large tumors.
- Open adrenal surgery is indicated for lesions contraindicated for or not amendable to minimally invasive techniques (e.g., large invasive carcinomas, great vessel involvement, severe cardiopulmonary diseases).
- All patients undergoing surgery for large adrenal masses must be counseled about the possibility of concurrent en bloc nephrectomy.
- It is recommended to perform a biopsy of the tumor either before or at the same session as ablative therapy.

Surgical, Radiographic, and Endoscopic Anatomy of the Female Pelvis

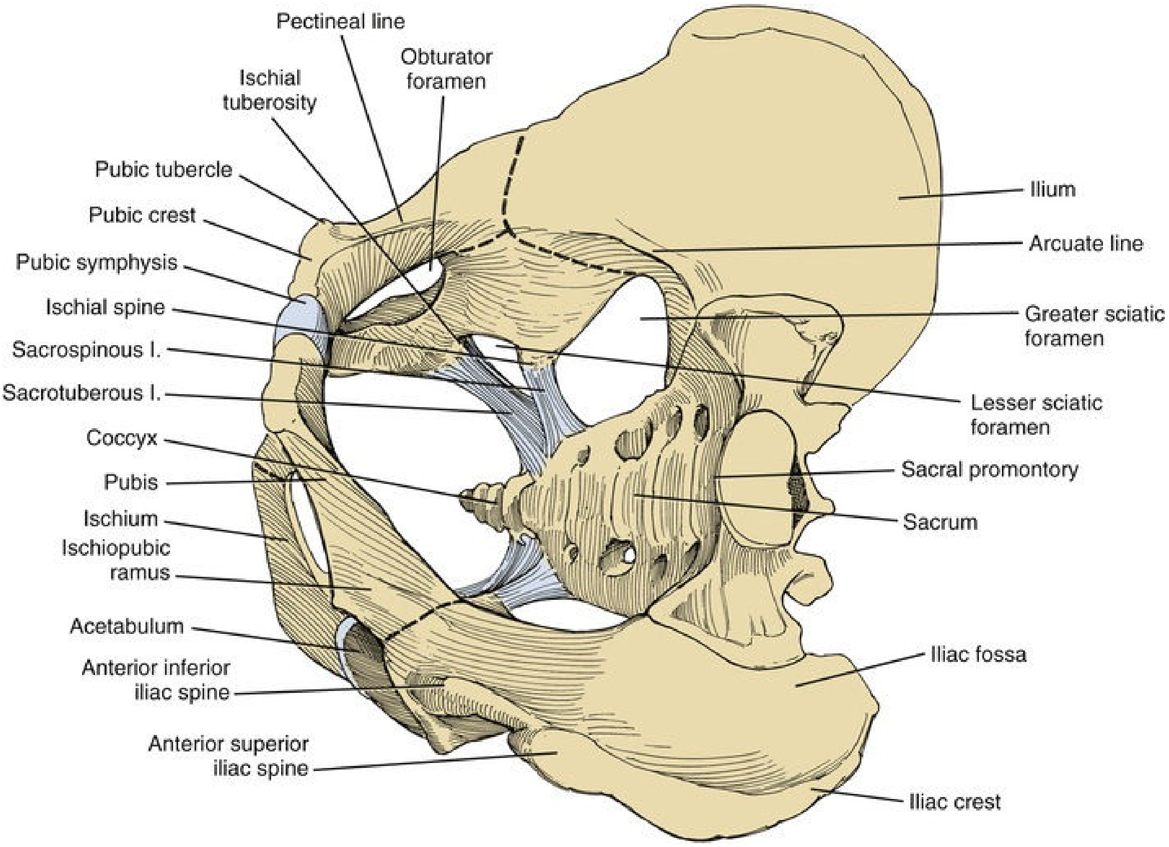
Priya Padmanabhan MD, MPH

The female pelvis is vital to locomotion and childbirth. These conflicting demands are fulfilled by a complicated urosurgical anatomy (Palastanga et al., 2006). There has historically been controversy over terminology and the function of the structures. This anatomy is not easily understood with pictures and descriptions alone because of the variability between individuals and indistinctness of some structures. This chapter focuses on aspects unique to the female pelvis, including surgical, radiographic, and endoscopic anatomic features.

Surgical Anatomy of the Female Pelvis

Bony Pelvis

The foundation of the female pelvic anatomy is the bony pelvis (Fig. 108.1), which is divided into two continuous compartments (true and false pelvises).



Pectineal line
Ischial tuberosity
Obturator foramen
Pubic tubercle
Pubic crest
Pubic symphysis
Ischial spine
Sacrospinous l.
Sacrotuberous l.
Coccyx
Pubis
Ischium
Ischiopubic ramus
Acetabulum
Anterior inferior iliac spine
Anterior superior iliac spine
Ilium
Arcuate line
Greater sciatic foramen
Lesser sciatic foramen
Sacral promontory
Sacrum
Iliac fossa
Iliac crest

FIG. 108.1 Bony pelvis. *l,* Ligament.

The true pelvis consists of four bones: two hip bones or innominate bones and the sacrum and coccyx. Each innominate bone is made up of the ilium, ischium, and the pubis. The ilium is the fan-shaped region of the hip bone that has a wing and body. The iliac crest is the rim between the anterior and posterior iliac spines. **During vaginal prolapse surgery, the ischial spine is an important landmark for identifying a safe location for fixation of apical suspension sutures.** The pubic rami, ischial spines, and sacrum are the main anchoring points for the ligamentous attachments supporting the pelvis. A line drawn between the ischial spines divides the anterior and posterior compartments.

The pelvis is divided into the true and false pelvis by an oblique line passing from the sacral promontory posterior to the superior margin of the pubic symphysis, corresponding with the iliopectineal line (Fig. 108.2). The pelvic brim defines the pelvic inlet. The true pelvis is the area below the pelvic brim, and the false pelvis is located above the brim.

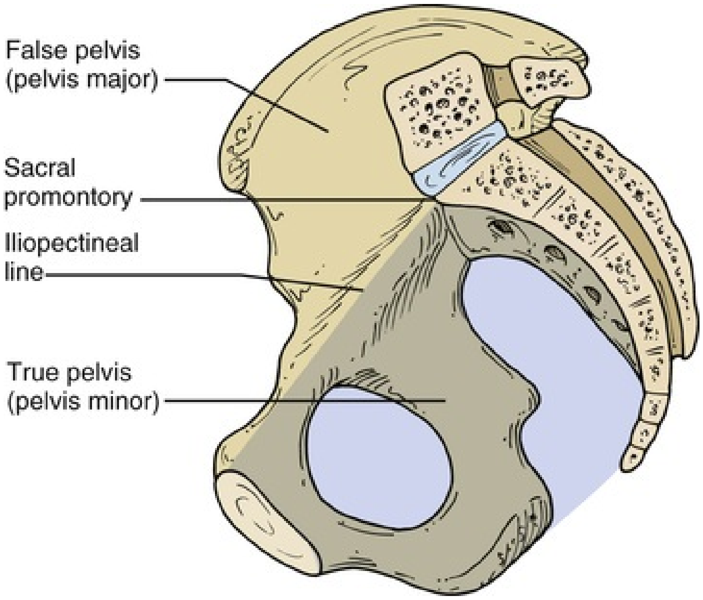


FIG. 108.2 Sagittal plane through the lateral pelvis. (From Goldstein C, Hagen-Ansert SL: *Textbook of diagnostic sonography,* ed 8, St. Louis, 2018, Mosby, pp 1049–1065.)

The principal differences in the female true and false pelvises include the following:

- The female pelvis is larger and broader with sides wider apart (Merry, 2005).
- The female inlet is oval (as compared with the heart-shaped male inlet) and wider, which contributes to the weakness of the pelvic floor (Herschorn, 2004).
- The angle between the inferior pubic rami is obtuse in women.
- The female sacrum is shorter and wider with a less pronounced sacral promontory (Schünke et al., 2006).

When a person is standing, the anterior superior iliac spine and pubic symphysis lie parallel to each other (Barber, 2005). **The pelvic inlet faces anteriorly, allowing pressure of the intra-abdominal and intrapelvic contents to be directed to the bony pelvis rather than the muscles and the fascia** (Fig. 108.3). This contrasts with surgical anatomy, which is commonly described in the lithotomy position.

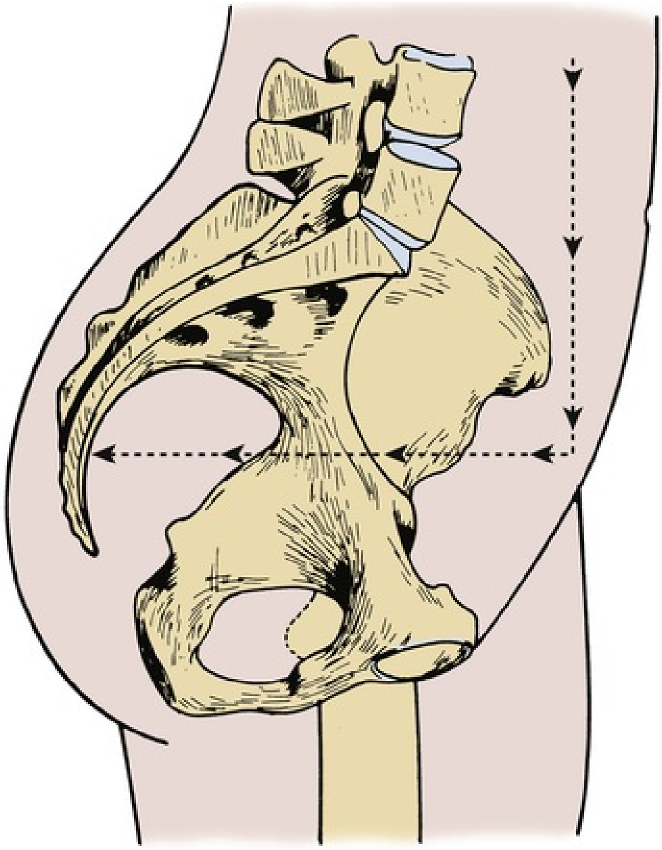

FIG. 108.3 Anterior-facing pelvic inlet.

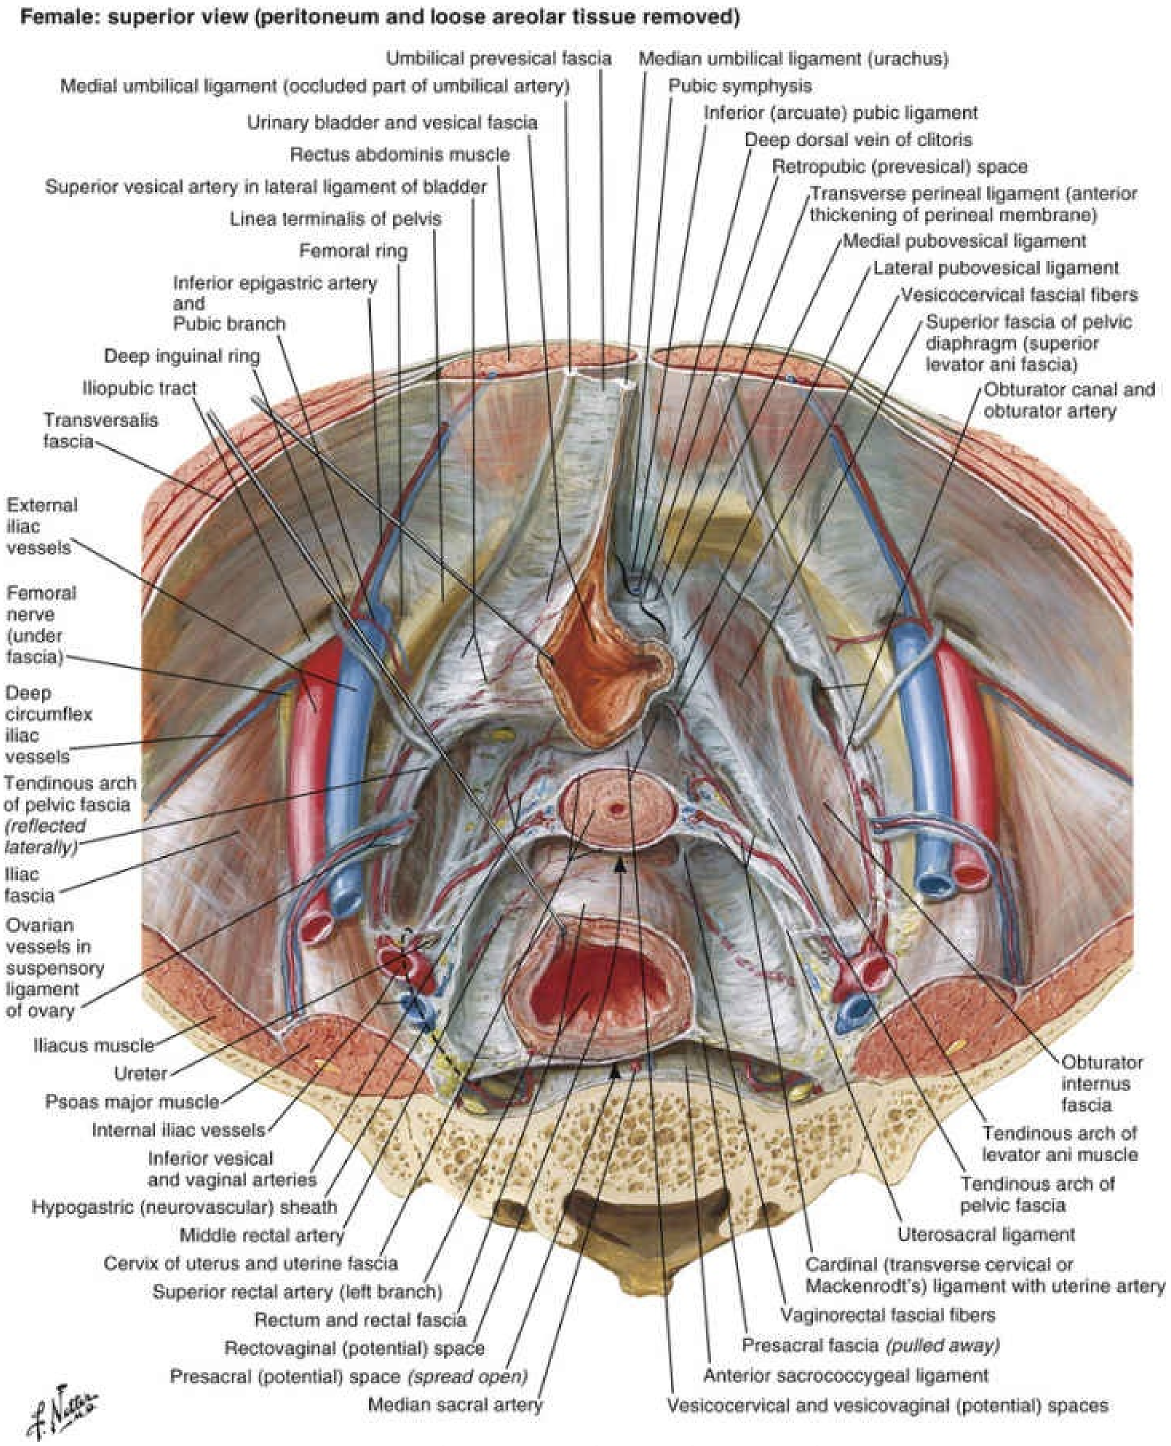
Fascia and Peritoneum

The fascia is divided into three strata: inner, intermediate, and outer. Rectus fascia, which is part of the inner strata, covers the anterior and lateral rectal wall, vessels, and nerves forming part of Denonvilliers fascia. The intermediate strata surround the uterus and supporting vessels. Most of the support of the pelvic organs comes from the retroperitoneal connective tissue, which is derived from the intermediate stratum. This includes the pubovesical and pubocervical fascia that surround the vagina. Fascia attached to the uterus is called the parametrium, and the fascia surrounding the vagina is called the paracolpium (Wei and DeLancey, 2004; Fig. 108.4).



Female: superior view (peritoneum and loose areolar tissue removed)
Umbilical prevesical fascia
Medial umbilical ligament (occluded part of umbilical artery)
Urinary bladder and vesical fascia
Rectus abdominis muscle
Superior vesical artery in lateral ligament of bladder
Linea terminalis of pelvis
Femoral ring
Inferior epigastric artery and Pubic branch
Deep inguinal ring
Iliopubic tract
Transversalis fascia
External iliac vessels
Femoral nerve (under fascia)
Deep circumflex iliac vessels
Tendinous arch of pelvic fascia *(reflected laterally)*
Iliac fascia
Ovarian vessels in suspensory ligament of ovary
Iliacus muscle
Ureter
Psoas major muscle
Internal iliac vessels
Inferior vesical and vaginal arteries
Hypogastric (neurovascular) sheath
Middle rectal artery
Cervix of uterus and uterine fascia
Superior rectal artery (left branch)
Rectum and rectal fascia
Rectovaginal (potential) space
Presacral (potential) space *(spread open)*
Median sacral artery
Median umbilical ligament (urachus)
Pubic symphysis
Inferior (arcuate) pubic ligament
Deep dorsal vein of clitoris
Retropubic (prevesical) space
Transverse perineal ligament (anterior thickening of perineal membrane)
Medial pubovesical ligament
Lateral pubovesical ligament
Vesicocervical fascial fibers
Superior fascia of pelvic diaphragm (superior levator ani fascia)
Obturator canal and obturator artery
Obturator internus fascia
Tendinous arch of levator ani muscle
Tendinous arch of pelvic fascia
Uterosacral ligament
Cardinal (transverse cervical or Mackenrodt's) ligament with uterine artery
Vaginorectal fascial fibers
Presacral fascia *(pulled away)*
Anterior sacrococcygeal ligament
Vesicocervical and vesicovaginal (potential) spaces
F. Netter M.D.

FIG. 108.4 Fascia: parametrium and paracolpium.

The transversalis fascia is part of the outer stratum and is continuous with the endopelvic and lateral pelvic fascia, which both play a key role at the exit points of the pelvic organs. The endopelvic fascia extends down from the uterine artery to the fusion of the vagina and levator ani. The iliac fascia is part of the outer stratum and covers the iliacus and psoas muscles. This attaches to the iliac crest and runs down to the tendinous arch (white line) and is continuous with the posterior part of the inguinal ligament, pectineal fascia, and obturator fascia. The obturator internus and piriformis muscles are covered by the obturator fascia.

The arcus tendineus fascia pelvis (ATFP), or arcus tendineus, is the thickened band of pelvic fascia running from the ischial spine to the pubic bone and serves **as a key point for fascial layer attachment.** The ATFP originates from the pubic bone laterally, pubovesical ligaments medially, and the tendinous arch of the levator ani (Fritsch et al., 2012). **The muscles of the levator ani attach to the arcus tendineus levator ani (ATLA).** The ATLA is the aponeurotic portion of the obturator fascia covering the obturator internus muscle.

The inferior pelvic fascia is continuous with the obturator fascia and fascia of the pudendal canal and covers the levator ani surface. The superior pelvic fascia arises from the outer stratum and obturator fascia. It runs from the pubic symphysis laterally to the ischial spine. The fascia is thinner over the muscles and organs, which allows for more mobility.

Spaces Among Pelvic Organs

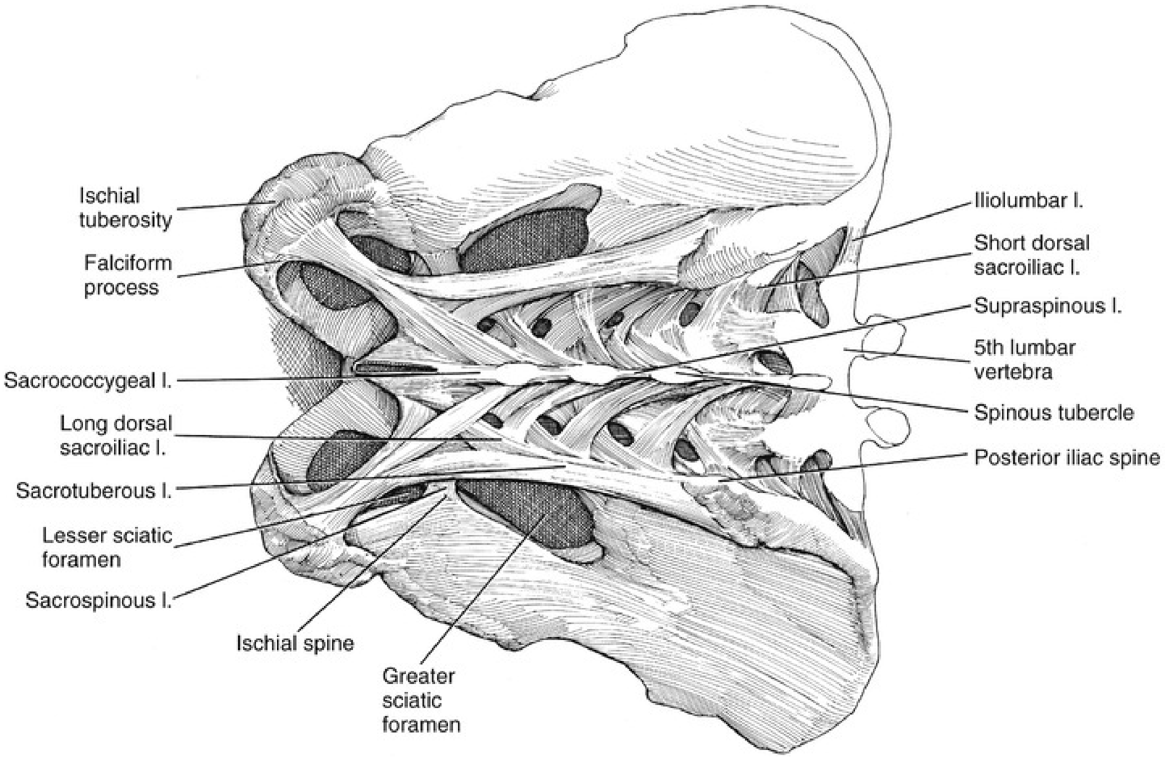
Six potential spaces exist among the female pelvic organs. The vesicovaginal and rectovaginal spaces are in the midline. The vesicovaginal space is contained by the bladder adventitia anteriorly and the vagina posteriorly. This space ends where the vagina fuses with the distal urethra and at the vesicocervical ligament (fusion of the bladder with the vagina and cervix). Another potential space is the prevesical space, which lies between the fascia covering the bladder and the endopelvic fascia behind the pubis. This space extends laterally to the obliterated umbilical artery. The retrorectal space is between the rectal fascia and the transversalis fascia over the sacrum. Laterally lie the paravesical and pararectal spaces, which are adjacent to their respective organs.

The pouch of Douglas, or rectouterine pouch, is formed by a fold of peritoneum (rectovaginal fold) that extends between the uterus and rectum. It is bound by the uterus, posterior vaginal fornix, rectum, and uterosacral ligaments.

The vesicouterine pouch is demarcated by a fold of peritoneum (uterovesical fold) reflected onto the bladder from the uterus at the junction of the uterine body and cervix. The peritoneum also forms the uterosacral folds between the pararectal and paravesical fossae.

Ligaments

The sacrospinous, sacrotuberous, and sacroiliac ligaments are significant to pelvic surgical anatomy. The sacrospinous ligament attaches from the ischial spine to the lateral border of the sacrum and crosses in front of the sacrotuberous ligament, fusing with it medially. The coccygeus muscle lies over the sacrospinous ligament. **The sciatic nerve and plexus cover the coccygeus muscle and must be avoided during vault suspension.** The sacrotuberous ligament runs from the posterior iliac spine along the sacral border and attaches to the ischial tuberosity. This attaches the ilium and ischium to the sacrum. The greater and lesser sciatic foramina run above and below the sacrotuberous ligament (Rosenblum et al., 2005). In addition, short and long dorsal sacroiliac ligaments connect the sacrum to the ilium posteriorly. The sacrospinous ligament lies in continuity with the sacrococcygeal ligament. The fifth lumbar vertebrae is connected to the ilium by the iliolumbar ligament (Fig. 108.5).

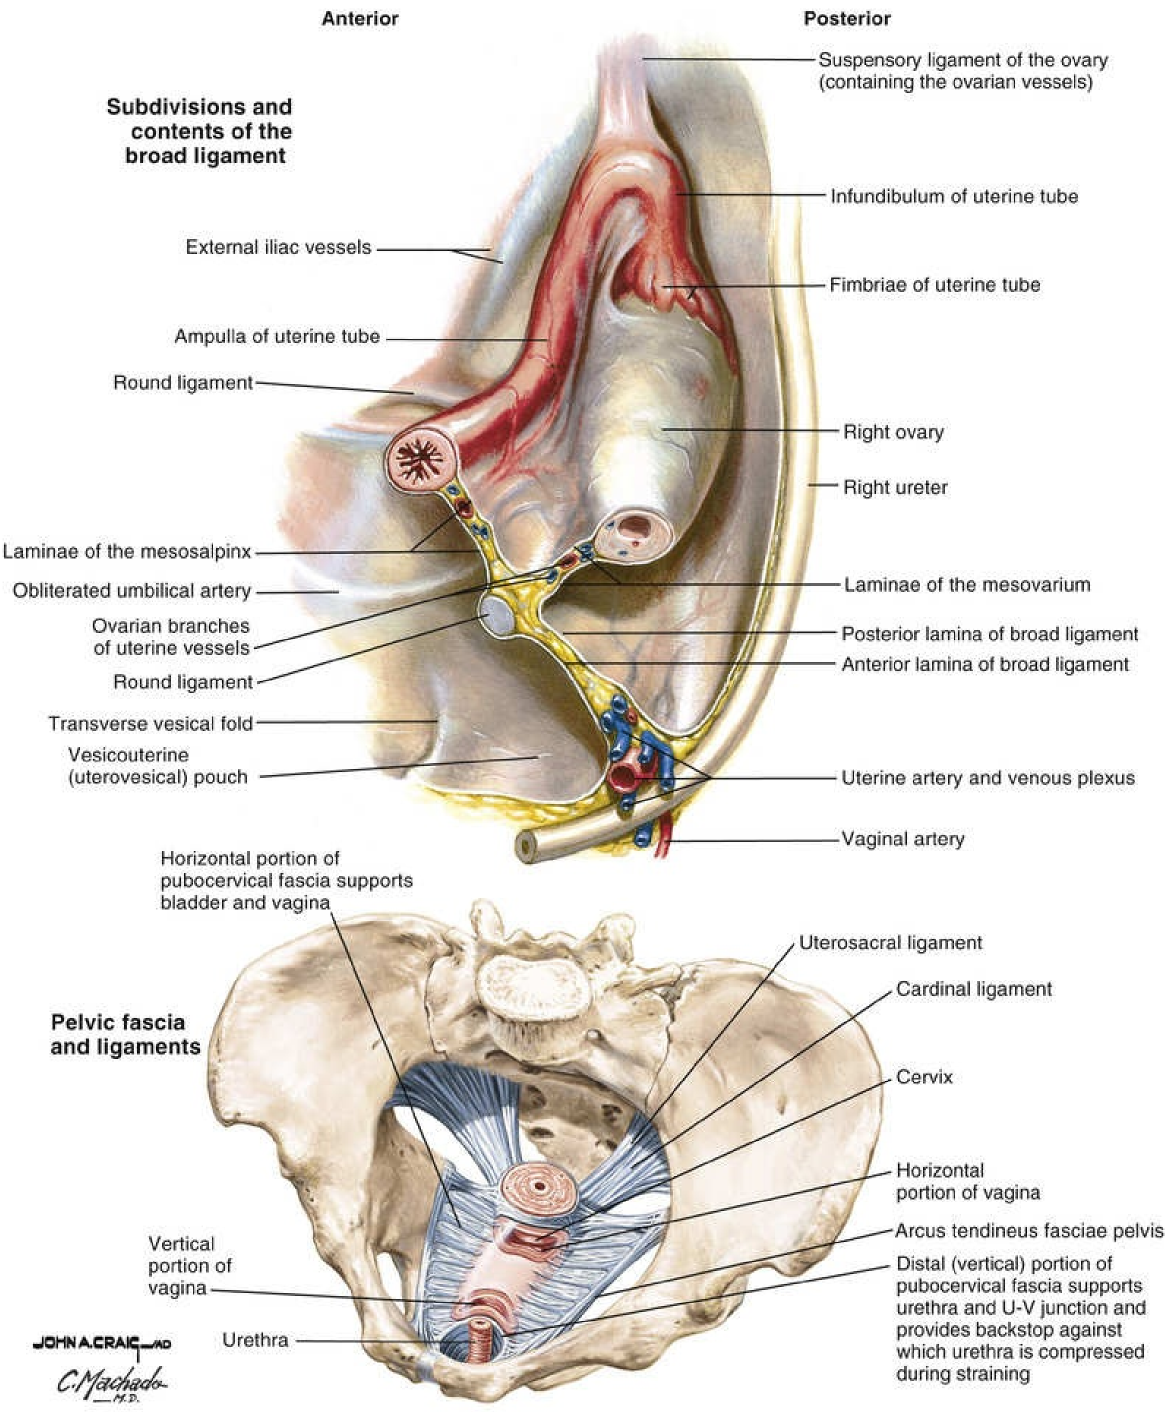


Ischial tuberosity
Falciform process
Sacrococcygeal l.
Long dorsal sacroiliac l.
Sacrotuberous l.
Lesser sciatic foramen
Sacrospinous l.
Ischial spine
Greater sciatic foramen
Iliolumbar l.
Short dorsal sacroiliac l.
Supraspinous l.
5th lumbar vertebra
Spinous tubercle
Posterior iliac spine

FIG. 108.5 Ligaments of the pelvis. *l,* Ligament. (From Maclenna GT: *Hinman's atlas of urosurgical anatomy,* ed 2, Philadelphia, 2012, Saunders.)

The pubovesical, vesicopelvic, cardinal, and uterosacral ligaments and pubocervical fascia are condensations of the transversalis fascia, which also help to support the pelvic organs. **The pubovesical ligaments (pubourethral ligaments) are analogous to the male puboprostatic ligaments and run from the pubic bone to the bladder neck, providing retropubic suspension.** They hold the bladder neck in place when it contracts and provide a hammock-like support for the mid-urethra in continuity with the anterior vaginal wall. The perivesical and endopelvic fascia fuse to form the vesicopelvic ligament or fascia. This extends from the base of the bladder and anterior vaginal wall and attaches to the tendinous arch. It is continuous with the periurethral fascia, cervix, and cardinal ligaments. **Defects in the vesicopelvic fascia can result in lateral cystocele defect** (Maclennan, 2012).

The broad ligament is formed by the peritoneum extending from the anterior and posterior surfaces of the uterus and contains the fallopian tube and ovary. It lies on the posterolateral surface of the uterus attaching it to the pelvic wall. The uterine artery, vein, and nerves lie within the mesometrium of the broad ligament. The mesosalpinx, a vascular network between the uterine tube and ovary, is also found within the broad ligament. **The round ligament exits at the internal inguinal ring and crosses over the external iliac artery, terminating in the mons pubis of the labium majus. The male homolog of the round ligament is the gubernaculum.** The round ligament attaches the lateral uterine body walls to the pelvic sidewalls and contains the ovarian ligaments. The infundibulopelvic ligament (suspensory ligament of the ovary) lies behind the broad ligament and runs from the ovary to the lateral surface of the uterus. This is beneath the entrance of the fallopian tube and contains the ovarian vessels (Fig. 108.6).



Anterior
Posterior
Subdivisions and contents of the broad ligament
Suspensory ligament of the ovary (containing the ovarian vessels)
Infundibulum of uterine tube
External iliac vessels
Fimbriae of uterine tube
Ampulla of uterine tube
Round ligament
Right ovary
Right ureter
Laminae of the mesosalpinx
Laminae of the mesovarium
Obliterated umbilical artery
Ovarian branches of uterine vessels
Posterior lamina of broad ligament
Anterior lamina of broad ligament
Round ligament
Transverse vesical fold
Vesicouterine (uterovesical) pouch
Uterine artery and venous plexus
Vaginal artery
Horizontal portion of pubocervical fascia supports bladder and vagina
Uterosacral ligament
Cardinal ligament
Pelvic fascia and ligaments
Cervix
Horizontal portion of vagina
Arcus tendineus fasciae pelvis
Vertical portion of vagina
Distal (vertical) portion of pubocervical fascia supports urethra and U-V junction and provides backstop against which urethra is compressed during straining
Urethra

C.Machado M.D.

FIG. 108.6 The broad ligament of the uterus and its contents.

The major supportive cardinal and uterosacral ligaments lie within the parametrium. Blood vessels, nerves, smooth muscle, adipose, and connective tissue lie near these ligaments. Nerves from the pelvic plexus travel with the vessels through the cardinal and uterosacral ligaments. **These structures are at risk during a hysterectomy and can lead to bladder dysfunction.** The uterosacral (sacrouterine ligaments) originate from the greater sciatic foramen and insert into the lateral aspect of the fascia encircling the cervix, isthmus of the uterus, and vaginal wall. They contain fibrous tissue and smooth muscle and are often used as anchoring structures in apical suspensions. **The ureter lies lateral to the anterior portion of the uterosacral ligament (closest at the cervix). There is potential for sacral nerve entrapment (S1 and S2 to S4 nerve trunks) during a suspension as the nerve crosses over the areas dorsally** (Ramanah et al., 2012).

The cardinal ligaments fuse posteriorly with the uterosacral ligaments and stabilize the uterus, cervix, and upper vagina (Fig. 108.7). They originate from S2 to S4 and insert into the posterolateral aspect of the pericervical fascia and lateral vaginal wall. Cardinal ligaments contain the major blood vessels form the internal iliac artery and run under the rectovaginal peritoneum.

Muscles of the Pelvic Floor

Pelvic Sidewalls

The walls of the pelvis are formed by the obturator internus, iliacus, psoas major and minor, levator ani complex, and the coccygeus. The obturator internus covers most of the lateral pelvic sidewall and passes through the lesser sciatic foramen and attaches to the greater trochanter of the femur. The piriformis muscle covers and pads the pelvic side walls posteriolaterally. This passes through the greater sciatic foramen and attaches to the greater trochanter of the femur. The sacral plexus is found medially.

Pelvic Floor

The pelvic floor is composed of the pelvic diaphragm, which extends from the pubis anteriorly to the coccyx posteriorly. The pelvic floor muscles are made up of the levator ani muscles and puborectalis. **The greatest part of the pelvic cavity floor is created by the broad, thin levator ani muscle, which plays a crucial role in support and function of the urogenital viscera.** This consists of the **iliococcygeus, puborectalis, and pubococcygeus muscles** and is innervated by the fourth sacral nerve. The name of each of its components is derived from its attachments. **The puborectalis muscle arises from the back of the symphysis pubis and the superior fascia of the urogenital diaphragm**, **runs**

backward alongside the anorectal junction, and joins its paired muscle on the opposite side, to form a U-shaped loop behind the rectum that slings the anorectal junction to the pubis. The puborectalis and levator muscles have reciprocal action. **The pubococcygeus muscle originates at the posterior portion of the pubis and arcus tendineus** and attaches to the visceral organs and anococcygeal raphe**.** The pubococcygeus is important in visceral control by forming a sling around the vagina and urethra, called the *pubovaginal muscles*. **The iliococcygeus muscle (also called the *coccygeus*) arises from the ischial spine and posterior part of the obturator fossa** and inserts on the last two segments of the sacrum, coccyx, and anococcygeal raphe. It sits anterior to the sacrospinous ligament. The coccygeus and iliococcygeus were previously thought to be innervated by divisions of the pudendal nerve, inferior rectal nerve, and perineal nerve. However, recent studies describe the innervation solely from the levator ani nerve originating from S3, S4, and S5 and traveling medial to the ischial spine and the ATLA. The opening of the levator ani muscle group is referred to as the levator hiatus and allows passage of the urethra, vagina, and rectum. **The levator plate is created by the fusion of the levator ani muscles in the midline and serves as a shelf on which the viscera rests.** Weakening of the levator ani muscles may cause this plate to sag, opening the hiatus and predisposing to pelvic organ prolapse (Barber, 2005; Boutros and Gordon, 2017; Herschorn, 2004).

The sustained resting tone of the pelvic floor muscles supports pelvic viscera, resists increases in intra-abdominal pressure, and is crucial in passive control of urinary and fecal continence. With loss of tone from muscle or nerve injury, there is laxity in the urogenital hiatus, which lessens the horizontal orientation of the levator plate (Barber, 2005; Fig. 108.9).

Vasculature

Arterial Supply

The internal iliac arteries (hypogastric arteries) extend into the pelvic cavity, along the posterior wall, and provide multiple branches that perfuse the bladder, uterus, vagina, and rectum. The uterus is supplied by the uterine artery, which arises from the anterior branch of the iliac artery. From the internal iliac artery, the uterine artery crosses above and anterior to the ureter, extending medially in the base of the broad and cardinal ligaments to the uterus at the level of the cervix. The tortuous uterine artery spirals up the side of the uterus and branches to anastamose with the ovarian artery and descends to supply the cervix and vagina. **The uterine artery passes in front of the ureter, making the ureter**

vulnerable to injury during division of the uterine pedicle, during a hysterectomy (Goldstein and Hagen-Ansert, 2018a).

Venous Supply

There are corresponding veins, usually multiple, that course with each arterial branch and drain into the internal iliac veins or larger veins. **Extensive venous plexuses are associated with the bladder, rectum, vagina, and uterus, called the *pelvic plexus of veins.*** The obturator vein lies posterior to the artery and ureter and drains directly into the internal iliac vein. The superior and inferior gluteal veins, lateral sacral veins, and middle rectal and rectal venous plexus drain into the internal iliac vein. The clitoral veins drain into the retropubic plexus. The retropubic plexus drains through the vesical plexus, lying over the anterior portion of the bladder (in continuity with the uterine plexus) and eventually drains in the internal iliac vein. The external iliac vein is a continuation of the femoral vein and drains the inferior epigastric vein and deep circumflex iliac and pubic veins (Fig. 108.10).

Lymphatic Drainage

Lymph nodes are difficult to appreciate on gross exam because they are hidden within the fatty and fibrous tissue of the intermediate stratum. Three major lymph node groups are associated with the pelvic vessels. **Most of the pelvic visceral lymphatic drainage passes through the internal iliac nodes and their branches: the presacral, obturator, and internal pudendal nodes.** The external iliac nodes are divided into three chains: external, middle, and internal. They lie lateral, anterior, and medial to the vessels. The external chain drains the anterior abdominal wall and clitoris. The bladder and vagina drain into the middle chain that lies over the external iliac artery. The internal chain drains the lower abdominal wall, superficial and deep inguinal nodes, bladder neck, and urethra. The inguinal nodes communicate directly with the internal and external iliac chains. The common iliac nodes receive efferent vessels from the external and internal iliac nodes and the pelvic ureter and drains in the lateral aortic nodes (Chung et al., 2016; Fig. 108.11).

Nerves of the Pelvis

The pelvis and the pelvic organs have somatic and autonomic innervation. The somatic innervation includes sensory and motor functions and relates to the external genitalia and the pelvic floor. The autonomic innervation provides sympathetic and parasympathetic nerves supply to the pelvic organs.

Somatic Innervation

The sacral plexus is formed from the ventral rami of spinal nerves L4-L5 and S1-S4 and lies on the piriformis muscle deep to the endopelvic fascia and posterior to the internal iliac vessels. **The sacral plexus exits the pelvis through the greater sciatic foramen immediately posterior to the sacrospinous ligament (SSL) and can be injured during a sacrospinous ligament**

culposuspension. The sacral plexus supplies motor and sensory innervation to the posterior thigh and lower leg. **The exaggerated lithotomy position may stretch the tibialis anterior muscle, innervated by the L4-S1 roots, through the sciatic and ultimately deep peroneal nerves, which can lead to foot drop.**

Pelvic and perineal branches of the sacral plexus include the posterior femoral cutaneous nerve (S2-S3) that passes through the greater sciatic foramen and has a sensory branch to the perineum. It also includes the pelvic somatic afferent nerves (L4-S4) from the ventral rami. They travel on the pelvic surface of the levator ani, innervating these muscles as well as the striated urethral sphincter.

The pudendal nerve arises from S2-S4 just above the sacrotuberous ligament and ischiococcygeus, passes through the greater sciatic foramen, and crosses the piriformis, ischiococcygeus, and SSL close to where it attaches to the ischial spine. The pudendal nerve is vulnerable to injury during an SSLF. The pudendal nerve next runs medial to the internal pudendal vessels as they travel through the lesser sciatic foramen into Alcock canal. The pudendal nerve branches into the (1) inferior rectal nerve, (2) perineal nerve, and (3) dorsal nerve of the clitoris. The perineal branch divides into the posterior labial branch, supplying the labium majus, superficial and deep transverse perineal muscles, external and anal sphincter, and levator ani. The pudendal branches carry efferent impulses to muscles of the pelvic floor and proprioceptive afferent signals and sensation from the urethra. Additional cutaneous innervation of the mons and labia is derived from the ilioinguinal nerves (L1), the genitofemoral nerves (L1 and L2), and of the perineum through the posterior femoral cutaneous nerve form the sacral plexus (S1-S3). The ilioinguinal nerve is at increased risk of injury during inguinal hernia repair, open appendectomy, c-sections, and total abdominal hysterectomies. The genitofemoral nerve may also be injured at time of inguinal herniorraphy or may occur during standard and extended lymphadenectomy. Some common causes for injury to the posterior femoral cutaneous nerve include gluteal pressure injury and pelvic tumors. **The pudendal nerve mediates perineal pain.**

Autonomic Innervation

Sympathetic innervation arises from preganglionic fibers at the T10-T12 level and supplies the ovaries and fallopian tubes through sympathetic fibers traveling along the ovarian vessels. The body of the uterus and cervix receive sympathetic innervation through the hypogastric plexus, accompanying branches of the iliac vessels, with fibers signifying stretching. **The superior**

hypogastric plexus arises from the aortic plexus below the aortic bifurcation at L5. It bifurcates into the left and right hypogastric nerves that unite with pelvic splanchnic nerves. The right and left pelvic (hypogastric) plexi lie near the bladder base, yielding the vesical plexus and uterovaginal plexus, which sends fibers through the broad ligament. The broad ligament acts as sensory tissue during sexual intercourse and assists with sensory function in micturition. Uterine pain is mediated through sympathetic afferent nerves passing up to T11/T12 and L1/L2 and is felt in the lower abdomen and high lumber spine.

The parasympathetic fibers lie deeper to the sympathetic fibers within the intermediate stratum and arises from the S1-S3 segments. These fibers control smooth muscle function of the bladder and anal sphincter systems (smooth muscle of the internal anal sphincter and striated muscle of the external anal sphincter). Cervical pain is mediated through the parasympathetic afferent nerves passing backward to S1-S2 (DeCosta, 2013).

Perineum

The perineum is divided into **two adjacent triangles. The anterior urogenital triangle** is bound by the pubic symphysis, the pubic rami, ischial rami, and deep transverse perineal muscles spanning the ischial tuberosities. **The posterior anal triangle** lies behind a line between the ischial tuberosities and contains the anus. **The urogenital triangle is divided into deep and superficial spaces by the perineal membrane.** The **perineal membrane (previously called the urogenital diaphragm) is a sheet of fascia lying between the two sides of the pubic arch.** The urethra and vagina pass through the urogenital hiatus of the perineal membrane to exit at the vestibule.

The deep space of the urogenital triangle contains the urethral sphincter, urethrovaginalis, compressor urethrae, and deep transverse perineal muscles. Urethrovaginalis is another name for the female external sphincter. The inferior fascia of the urogenital diaphragm is what lays the groundwork for the deep space. **The superficial space is made up of the superficial perineal muscles, clitoris, vestibular bulbs, and Bartholin glands.** The vestibular bulbs or corpus spongiosum tissue are two elongated erectile bodies on either side of the urethra, close to the labia minora.

Colles fascia forms the roof of the superficial perineal space. Laterally, this fascia is firmly attached to the fascia lata of the thigh at the ischiopubic ramus and defines the perineal thigh crease. The apex is attached to the arcuate ligament of the pubis. Posteriorly, the fascia surrounds the superficial transverse perineal muscle and anchors to the inferior fascia of the urogenital diaphragm, fusing with the perineal body. Anteriorly, Colles fascia covers the clitoris similar to dartos in the male. The deep perineal fascia lies over the superficial muscles of the perineum and fuses with the suspensory ligaments of the clitoris and fascia of the rectus sheath and external oblique muscles.

The perineal body contains muscle and collagenous and elastic fibers and is at the central point of the perineum. **It is the convergence of the bulbospongiosus, external anal sphincter, and superficial and deep transverse perineal muscles.** The perineal body attaches to the posterior border of the perineal membrane. It is posterior to the vestibule of the vagina and anterior to the anal canal. Damage to the perineal body during parturition can cause damage to fibers of the external anal sphincter. Episiotomy is angled laterally to avoid damage to these fibers (Howard and Dickie, 2018).

The bulbospongiosus muscle splits to surround the introitus and attaches anteriorly to the clitoris. This muscle attaches to the perineal body and covers the vestibular bulbs. The bulbospongiosus muscle bodies contract to constrict the vaginal orifice and express vestibular gland secretions. The ischiocavernosus muscle also covers one crus of the clitoris and promotes its erection. The superficial transverse perineal muscles overlie the posterior portion of the vagina (Fig. 108.12).

Anal Perineum

The rectum is covered in pararectal fascia that attaches the anorectal junction to the sacrum. Anteriorly there is the rectovesical fascia and posterolaterally there are lateral ligaments of the rectum that run with the middle rectal vessels. The anococcygeal ligaments also provide anal canal support and run between the middle of the external anal sphincter and the coccyx.

The ischiorectal fossa contains fat and Colles fascia and is bound by the external anal sphincter, ischial tuberosity, urogenital diaphragm, and gluteus maximus. The internal pudendal vessels run along the lateral wall of the ischiorectal fossa inside Alcock canal. Alcock canal, also called the pudendal canal, is made up of fascia of the obturator internus muscle and contains the internal pudendal vessels and pudendal nerve. The internal rectal venous plexus lies between the rectum, puborectalis, and levator ani muscles. The external plexus lies deep to the sphincters. They both drain into the middle rectal vein. The superior rectal vein drains into the inferior mesenteric vein, and the inferior rectal vein drains into the pudendal vein.

The longitudinal muscles of the rectum continue into the anus as the intersphincteric plane demarcating the line between the internal sphincter and external sphincter fibers. **The external anal sphincter is composed of striated muscles and has three parts.** From distal to proximal, these components include the subcutaneous external anal sphincter, the superficial external sphincter, and the deep external sphincter. The deep external anal sphincter is adjacent to the deep transverse perineal muscles and the levator ani. The external anal sphincter is innervated by the inferior rectal nerve and by branches of the pudendal nerve. **The internal anal sphincter is circular nonstriated muscle lying outside the internal rectal venous plexus.** It receives autonomic innervation from iliohypogastric plexus branches. Fecal incontinence is complex and depends on the integrated function of the internal and external anal sphincters, the puborectalis muscle, intact neurosensory pathways, rectal compliance, anorectal sensation, and anal sphincter resting tone (Lin, 2013; Fig. 108.13).

External Genitalia

The perineal membrane is pierced by the vagina and urethra. **The crura of the clitoris and the bulbs of the vestibule are covered by the ischiocavernosus and bulbospongiosus muscles, respectively.** The crura and vestibular bulbs make up the erectile tissue, which attaches to the inferior surface of the perineal membrane. The right and left crura attach to the medial margins of the ischiopubic rami to form the shaft of the clitoris. These bodies turn downward and backward to the urethral opening and are capped by the glans of the clitoris. The paired vestibular bulbs surround the urethral and vaginal openings. They taper and fuse in the midline, terminating with the glans. The posterior end of each bulb is expanded and covers the greater vestibular (Bartholin) gland. This gland can be the site of cyst formation (Bartholin gland cyst) or become infected (Bartholin abscess), requiring surgical intervention.

The skin folds, labia majora, are the most superficial parts of the female external genitalia. These meet anteriorly at the mons pubis. The mons pubis is a pad of fat overlying the pubis symphysis and covering most of the clitoris. The two labia minora lie between the labia majora and become more prominent anteriorly. **The labia minora fuse in the midline, forming two folds of skin around the glans of the clitoris. The hoodlike anterior fold becomes the prepuce of the clitoris, and the smaller posterior fold forms the frenulum.** Posteriorly, the labia minora come together at the fourchette, which is usually torn during vaginal delivery. **The labia minora encloses a cleft, the vestibule, into which the vagina and urethral meatus open.** The vaginal opening or introitus, is an anteroposterior slit, surround by a fringe of skin, the hymen. The external urethral meatus lies 1 cm anterior to the vaginal opening.

The term *vulva* describes the mons pubis, the labia major and minora, clitoris, and vestibule (Gosling et al., 2017). The vulva has lymphatic drainage into the superficial inguinal glands, which drain to the deep inguinal nodes that travel to the pelvic nodes. The clitoris and labia minora drain to the deep inguinal nodes and may pass to the internal iliac nodes.

The innervation of the anterior labium majus derives from branches of the ilioinguinal nerve, which arises from T12. Branches from the perineal nerve innervate the posterior two-thirds of the labia. Laterally, there is also innervation from the perineal branch of the cutaneous nerve of the thigh. Parasympathetic stimulation leads to increased vaginal secretions, erection of the clitoris, and engorgement of the erectile tissues (Figs. 108.14 and 108.15).

Female Pelvic Organs

The uterus is normally anteverted and anteflexed and composed of the uterine body and the cervix. The cervix terminates as the os into the vagina. It is surrounded by the vaginal wall that is shallow anteriorly (ventral fornix) and deeper posteriorly (dorsal fornix) along with lateral fornices. The cervix is usually 2.5 cm long, adjacent to the bladder, and separated by the parametrium. The body of the uterus is composed of three layers. **The outermost layers is the perimetrium, consisting of the peritoneum and thin connective tissue (parametrium). The myometrium is broken down into three additional layers: outer longitudinal layer continuous with the ovarian and round ligament, middle circular layer, and inner longitudinal layer. The blood**

vessels and nerves are located in this layer. The inner most layer of the uterus is the mucosal layer or endometrium.

The uterine artery branches off the anterior branch of the internal iliac artery. It crosses the ureter close to the cervix and provides a small branch to the ureter. The uterine artery passes through the broad ligament and feeds the fallopian tube and runs from lateral to medial to join the ovarian artery. The cervical branches terminate in the vaginal branches of the uterine artery or azygous arteries of the vagina. The uterus drains into a uterine plexus that runs in the broad ligament and joins the vaginal and ovarian plexuses to drain ultimately into the internal iliac vein. **The uterine innervation originates from the inferior hypogastric plexus. Uterine lymphatic drainage is complex.** The cervix drains into the external and internal iliac nodes and the sacral nodes. The upper part of the uterus and fallopian tubes follow the ovarian drainage into the lateral aortic and preaortic nodes. Around the round ligament, there is uterine drainage into the superficial inguinal nodes. The uterine body drains into the external iliac nodes. The fundus drains into the para-aortic and lateral aortic nodes (Fig. 108.16).

The fallopian tubes are 10 to 12 cm in length and are draped in the broad ligament. They open posteromedially and are divided into four parts:

uterine interstitial segment, isthmus, ampulla, and infundibulum. The fallopian tubes enter the uterus bilaterally at the uterine cornua (or horns) and terminate with fimbriae. The arterial blood supply is from the ovarian and uterine arteries. The lateral two-thirds of the fallopian tubes drain into the ovarian veins, and the medial portion drains into the uterine plexus. Lymphatic drainage is to the para-aortic nodes (ovarian vessels), internal iliac chain (uterine vessels), and inguinal nodes (round ligament). Innervation is by autonomic fibers from the ovarian and uterine plexuses.

The ovaries are supported by the mesovarium in the ovarian fossa within the posterior peritoneum, bordered by the obliterated umbilical artery, ureter, and internal iliac artery. The ovary is attached to the posterior aspect of the broad ligament and is suspended by the infundibulopelvic ligament, which contains the ovarian vessels. The ovary is also attached to the uterus by the ovarian ligament. The ovarian artery arises directly from the aorta and passes in the infundibulopelvic ligaments into the hilum of the ovary. The artery then passes through the broad ligament, supplying the fallopian tube, and joins the uterine artery. The venous drainage of the ovary is to a pampiniform plexus, merging into the ovarian vein. **The right ovarian vein drains directly into the vena cava below the renal vein, and the left ovarian vein drains into the left renal vein.** Innervation is from the ovarian and inferior mesenteric plexuses, following the path of the ovarian artery. The lymphatic drainage, like the testicle, is into the lateral aortic and preaortic nodes near the kidneys.

Columnae rugarum, or vaginal columns of mucosa, run along the anterior and posterior vaginal walls of the vagina, which terminate at the urethrovaginal ridge or carina. These ridges create an H shape on cross-section with rugae or folds. The vagina is composed of a mucous membrane and lamina propria that are fixed to the muscular layer. The muscle has an outer longitudinal and inner circular layer that are attached to the rectovesical fascia bilaterally. The muscle is lined by nonkeratinized, stratified squamous epithelium. **The vaginal wall is attached to the cervix higher on the posterior wall compared with the anterior wall; thus the anterior wall is 7.5 cm and the posterior wall is 9 cm on average. The vagina is attached anteriorly by the levator ani to the arcus tendineus and posteriorly to the rectovaginal septum.** The apex is covered by the peritoneum form the rectouterine pouch. The base of the bladder is tethered on the vaginal wall by smooth muscle fibers. These must be opened to access the vesicovaginal space, as needed for repair of a vesicovaginal fistula. **The ureters pass close to the lateral fornices of the**

vagina and are anterior to the vagina as they enter the bladder. Access to the retropubic space can be obtained by incising the anterior vaginal wall on either side of the urethra, which is the typical dissection for a retropubic sling.

The vaginal vessels (from the internal iliac artery) and nerves (branch of pudendal nerve called *deep perineal nerve*) lie on the anterolateral surface of the vagina deep to the ATFP. The uterine arteries supply the superior part of the vagina. The middle and inferior portion of the vagina are supplied by the vaginal arteries (branches of the uterine and middle rectal artery). The inferior portion is supplied by the internal pudendal artery. The vaginal venous plexus joins the uterine plexus to form the uterovaginal venous plexus. The lymphatic drainage into the internal and external iliac lymph nodes lies at the superior portion of the vagina. The middle portion drains into the internal iliac lymph nodes and the inferior portion into the sacral, common iliac, and superficial inguinal nodes.

The vagina has autonomic innervation from the uterovaginal plexus (sympathetic, parasympathetic, and visceral afferent fibers), which travels at the base of the broad ligament. **The lower one-fourth of the vagina has somatic innervation from the pudendal nerve and is sensitive to touch and temperature change.**

Pelvic Organ Support

The pubovesical ligaments help support the urethra and bladder neck but may also play a role in relaxation of the bladder neck during micturition (Herschorn, 2004). **The anterior vagina provides support to the urethra through its lateral attachments to the pubococcygeus and ATFP.** The pubocervical fascia that extends from the pubic symphysis to the cervix may provide additional support to the bladder base (Herschorn, 2004).

The parametrium and paracolpium provide support to the vagina and uterus. The cardinal ligaments and uterosacral ligaments provide additional support to the uterus, cervix, and vagina. This was described by DeLancey as Level 1 support (Wei and DeLancey, 2004), which supports the uterus and vaginal apex. The broad and round ligaments do not play a significant role in pelvic organ support (Barber, 2005). Weakness of the lateral attachments of the cardinal ligaments or vesicopelvic ligaments leads to lateral cystocele defects. The posterior vaginal wall is supported by the paracolpium that attaches to the rectovaginal fascia (Herschorn, 2004). This sheet of fascia at the medial aspect of the vagina is sometimes referred to as the rectal pillars (Ashton-Miller and

DeLancey, 2007). **Level II support runs from the paravaginal attachments to the ATFP and to the arcus tendineus rectovaginalis** (Barber, 2005)**. Anterior wall prolapse results from loss of level II support (anterior vaginal wall support). Level III support is created by the distal vagina attachments to the levator muscles laterally, anteriorly to the urethra, and posteriorly to the perineal body. Level III support provides foundation to the urethra, and disruption leads to urethral hypermobility** (Fig. 108.17).

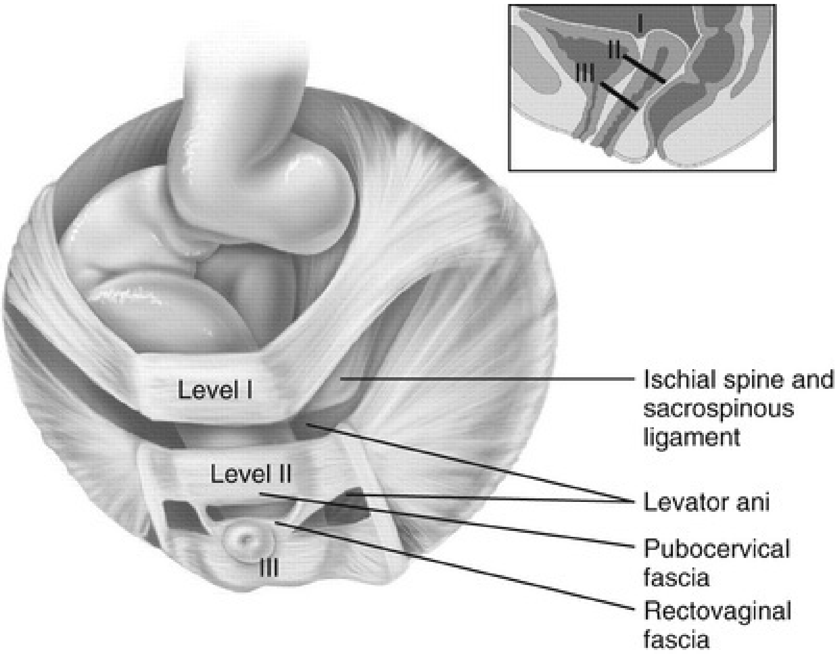

FIG. 108.17 Vaginal and visceral supportive structures as defined by Delancey. The fibers of level I support are oriented vertically and suspend the uterus and upper vagina. Level II support is more horizontal in its orientation and is attached to the mid-vagina. Distally, level III support fuses directly into support structures. (From Delancey JO: Anatomic aspects of vaginal eversion after hysterectomy. *Am J Obstet Gynecol* 166:1717–1728, 1992.)

Urethra

The adult female urethra is about 4 cm long and 6 mm in diameter. It runs anteroinferiorly behind the pubic symphysis, embedded in the anterior vaginal wall. It is suspended beneath the pubis by the posterior pubourethral ligaments and anteriorly by the suspensory ligaments of the clitoris. The urethra crosses the perineal membrane and ends at the external urethral orifice in the vestibule as an anteroposterior slit, anterior to the opening of the vagina and 2.5 cm behind the glans clitoris. Aside from urine passage, the anterior and posterior walls of the urethra are in apposition. Exceptions to this include congenital defects, such as hypospadias, when the urethra opens into the vagina and in epispadias, where there is a fissure in the upper wall of the urethra.

The wall of the female urethra consists of an outer, circular muscular layer and inner, longitudinal mucosal layer, which lines the lumen and is continuous with the bladder mucosa and constitutes the involuntary urethral sphincter. The female internal sphincter is a continuation of the detrusor muscle and is made of smooth muscle, which is under involuntary or autonomic control. The female external sphincter is anatomically separate from the adjacent periurethral striated muscles of the anterior pelvic floor. These muscle layers are surrounded by elastic tissue and collagen. The longitudinal fibers shorten the urethra and increase the diameter during voiding (Maclennan, 2012; Standring, 2016). **At the distal two-thirds of the urethra, the voluntary sphincter is present, composed of striated muscle. At the most proximal portion (mid-urethra) it forms a horseshoe around the urethra. This is where the closing pressure is highest.** There are muscle fibers on the lateral sides of the urethra, which are continuous with the anterior and lateral walls of the vagina (urethral compressor). When they contract, the urethra closes against the anterior vaginal wall. The additional fibers surrounding the urethra and vagina compose the urethrovaginal sphincter. When these fibers contract, they tighten the urogenital hiatus. The pubococcygeus runs along the urethra bilaterally and increases the resistance in the urethra.

There are many periurethral glands, which, when obstructed, may give rise to urethral diverticula or other cysts (see Fig. 108.23). The most prominent are Skene glands (homologous with the prostate), which open distally just inside the meatus.

The urethra is composed of three anatomic layers: (1) epithelium, (2) submucosa, and (3) mucosa. The lamina propria is a thin layer of connective tissue that forms part of the moist lining of the mucosa. The urethra is made up of transitional epithelium with multiple infoldings that allow distensibility and coaptation on closure. The epithelium transitions to pseudostratified and squamous epithelium at the most distal portion of the urethral. The epithelium is surrounded by spongy tissue of vascular networks that make up the submucosa. Surrounding the urethra is a thin periurethral fascia. An infected or ruptured paraurethral gland, disrupting the periurethral fascia leads to a urethral diverticulum. **The mucosa and submucosa are primarily responsible for urethral closure pressure and are estrogen dependent.**

The urethra is primarily supplied by the vaginal artery yet also receives some arterial supply from the inferior vesical artery and internal pudendal arteries. The venous drainage is carried through the inferior, middle, and superior vesical veins, as well as the clitoral plexus into the internal pudendal veins. The distal one-third of the urethra (anterior urethra) drains into the superficial and deep inguinal lymph nodes. The proximal two-thirds (posterior urethra) drains into the iliac and obturator lymph nodes (Fig. 108.18).

Key Points: Surgical Anatomy of the Female Pelvis

- The pelvic inlet faces anteriorly, allowing pressure of the intra-abdominal and intrapelvic contents to be directed to the bony pelvis rather than the muscles and the fascia. The bony pelvis should be visualized in the supine position.
- The ATFP and ATLA are two distinct structures serving as key players in fascial attachment. ATFP is the main point for fascial attachment. The

levator ani muscles attach to the ATFP and cover the obturator internus.

- The ischial spine and sacrospinous ligament are important landmarks during vault suspension to avoid injury to the sacral plexus and pudendal nerve.
- The sustained resting tone of the pelvic floor muscles (pubococcygeus, puborectalis, and iliococcygeus) supports pelvic viscera, resists increases in intra-abdominal pressure, and is crucial in passive control of urinary and fecal continence.

Radiographic Anatomy of the Female Pelvis

Different modalities are used to visualize female pelvic anatomy and its contents.

Ultrasound

Ultrasound (US) is a readily available, important diagnostic tool for evaluation of pelvic anatomy and pathology in adult and pediatric populations. It is a noninvasive, high-resolution imaging technique with ability to separate fluid from soft tissue (Goldstein and Hagen-Ansert, 2018b). Transabdominal, transperineal, transrectal, translabial, and transvaginal approaches have been used (Dietz, 2008).

Transperineal or translabial US is often used because of its noninvasive approach, which does not distort or compress underlying structures. The pubic symphysis, urethra, bladder neck, vagina, rectum, and anal canal are commonly seen on translabial US (Fig. 108.19). The levator plate and pubovisceral muscles are a hyperechogenic area behind the anorectal junction (Dietz, 2004). The cul-de-sac contains fluid, fat, or small bowel. Bladder neck mobility may be assessed via real-time imaging while performing a Valsalva maneuver in the supine position. Bladder wall thickness and pelvic organ prolapse can be measured via translabial US (Dietz, 2004). **Other common uses of ultrasound include visualization of transvaginal mesh, urethral bulking agents, and urethral implants.** Newer probes have allowed for three-dimensional imaging reconstruction, which provides the added benefit of visualizing structures in the axial view rather than only the midsagittal view (Fig. 108.20).

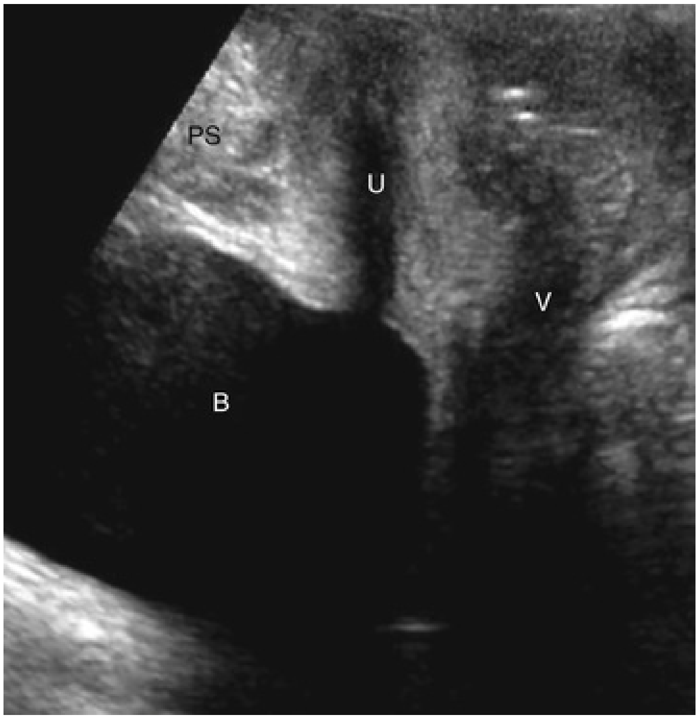

FIG. 108.20 Two-dimensional translabial ultrasound; image in the midsagittal plan. *B,* Bladder; *PS,* pubic symphysis; *U,* urethra; *V,* vagina.

Anorectal ultrasonography is useful for evaluation of anal sphincter defects in associated fecal incontinence. Internal sphincter defects are seen as an echogenic discontinuity in the hypoechoic muscle between the vagina and the rectum (Hull and Zutshi, 2008). External sphincteric injury appears as a hypoechoic lesion in a normally echogenic structure. A sphincter in spasm or that is hypertrophied (as in obstructed defecation) can appear thickened (Fig. 108.21).

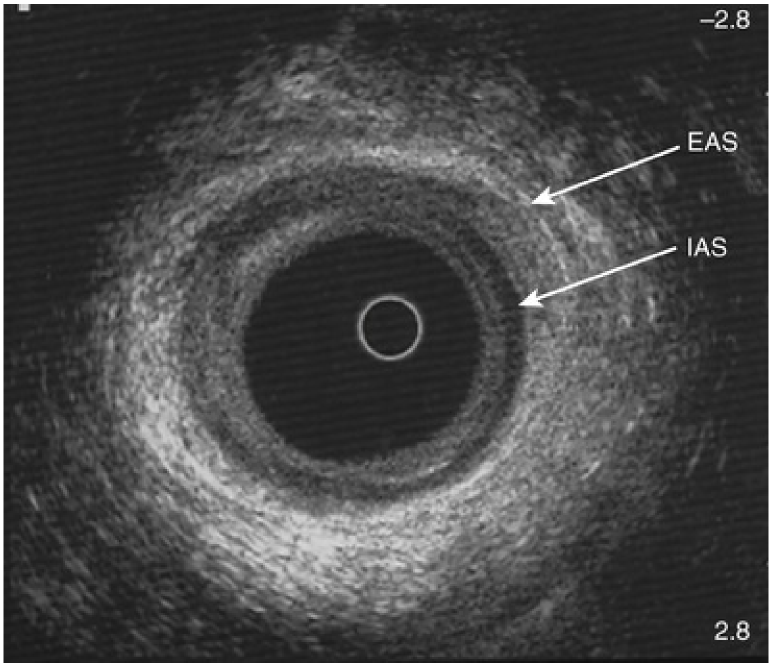

FIG. 108.21 Endoanal ultrasound imaging in a normal female. *EAS,* External anal sphincter; *IAS,* internal anal sphincter.

Pelvic Magnetic Resonance Imaging

Magnetic resonance imaging (MRI) is the most comprehensive and conclusive imaging modality available to image the female pelvis without the use of radiation. This modality provides well-delineated images of tissue based on different water content, such as muscle, fat, fluid, and blood (Roth and Deshmukh, 2018). For pelvic floor imaging, the half-Fourier acquisition single-shot turbo spin-echo (HASTE) or single-shot fast spin-echo (SSFSE) T2-weighted sequences are often used. These provide quick, noninvasive multiplanar surveys of the abdomen and pelvis and dynamic studies of the pelvic floor during relaxed or strained states (Raman and Boyadzhyan, 2008a). The obturator internus and levator ani muscles are well visualized by MRI (Fig. 108.22). T1-weighted imaging with gadolinium contrast is useful for visualization of the kidneys and ureters. T2-weighted imaging is useful to differentiate and assess masses, cysts, and tissue parenchyma.

Rectum

FIG. 108.22 Axial T2 half-Fourier acquisition single-shot turbo spin-echo magnetic resonance imaging of normal female pelvic anatomy.

Pelvic MRI can differentiate cystic lesions in the vagina and urethra. Common benign vaginal cysts include müllerian cysts, epidermal inclusion cysts, Gartner duct cysts, Bartholin gland cysts, and Skene gland cysts (Fig. 108.23). **T2-weighted MRI is the best imaging technique to visualize and localize urethral diverticula and to differentiate them from other benign vaginal masses** (Walker et al., 2011).

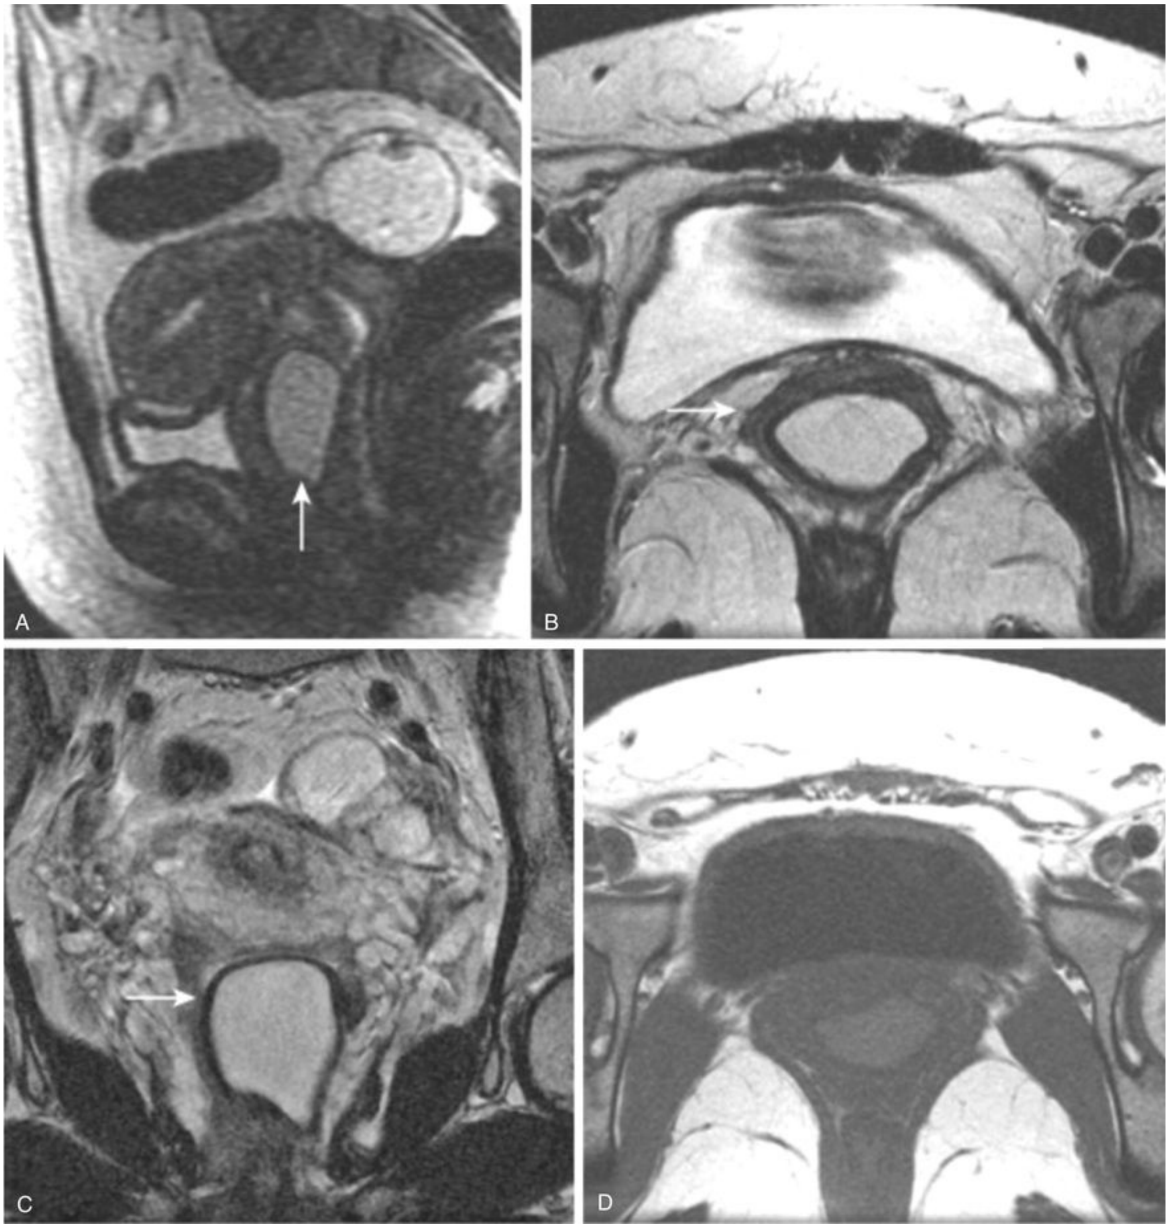

FIG. 108.23 Benign cystic lesions. (A) Garner duct cyst (T2-weighted image with uniformly hyperintense lesion in upper vagina). (B) Bartholin gland cyst (T1-weighted hyperintense lesion in lateral vagina). (C) Müllerian duct cyst (T2-weighted fat suppressed image shows a large septated cystic lesion in the upper vagina). (D) Skene gland cyst (T2-weighted image; a small cystic structure abutting the distal urethra). (In MRI of the Uterus, Cervix and Vagina in Fundamentals of the Uterus, Cervix and Vagina In Fundamentals of Body MRI. Chapter 9. 2018; pp 334–395.)

On T2-weighted MRI, the uterus is delineated into three zones; endometrium, junctional zone and myometrium (Fig. 108.24). The endometrium and uterine cavity have high signal, whereas the junctional zone has low signal. The outer myometrium has medium to high signal. The most common indications for MRI include identification and characterization of leiomyomata, assessment of leiomyoma treatment response, and for staging of endometrial and cervical malignancies (Roth and Deshmukh, 2018).

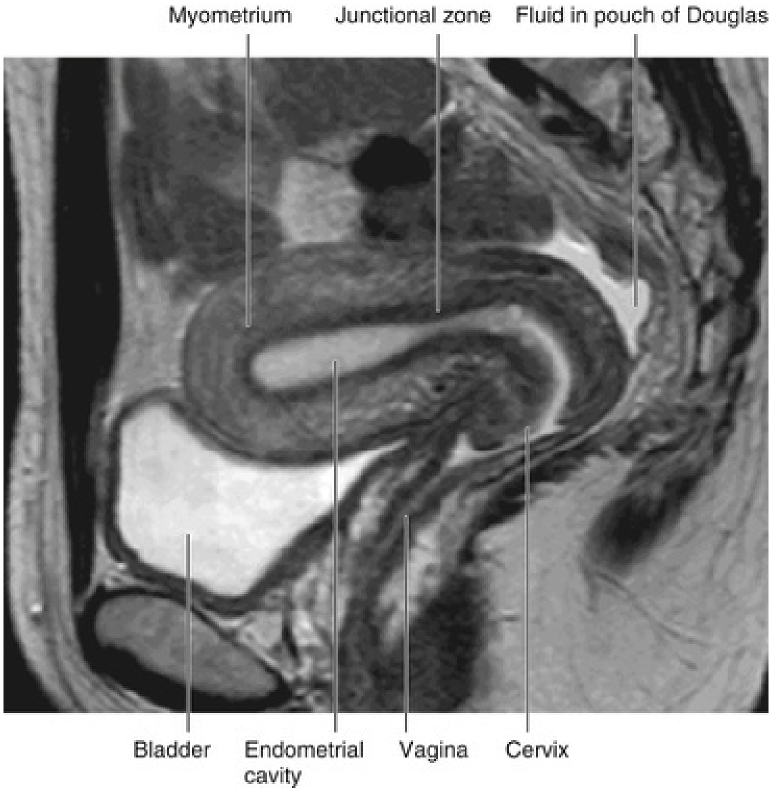

FIG. 108.24 Normal anatomy of the pelvic structures on T2-weighted magnetic resonance image showing the zonal anatomy of the uterus. (From Standring S: *Gray's anatomy: the anatomical basis of clinical practice,* ed 40, London, 2008, Churchill Livingstone.)

MRI can be used for the diagnosis and staging of pelvic organ prolapse. Midsagittal and parasagittal resting and straining supine views are obtained for evaluating the different compartments, pelvic floor muscles, and pelvic organs (Fig. 108.25). These images are often looped as a cine stack and are measured to fixed anatomic landmarks to determine the grade of pelvic organ prolapse and pelvic floor relaxation (Comiter, 2005). Measurements obtained include the “H-line,” or levator hiatus width, measured from the pubis to the posterior anal canal. The “M-line” (muscular pelvic floor relaxation) runs perpendicular from the pubococcygeal line (PCL) to the lowest aspect of the H line and relates to the descent of the levator hiatus from the PCL. The "O" classification is then assigned to the degree of prolapse beyond the "H-line" as 0, 1, 2, or 3 (no, mild, moderate, or severe). The midpubic line is the line drawn through the midline longitudinal axis of the pubic symphysis (Comiter, 1999; Fig. 108.26).

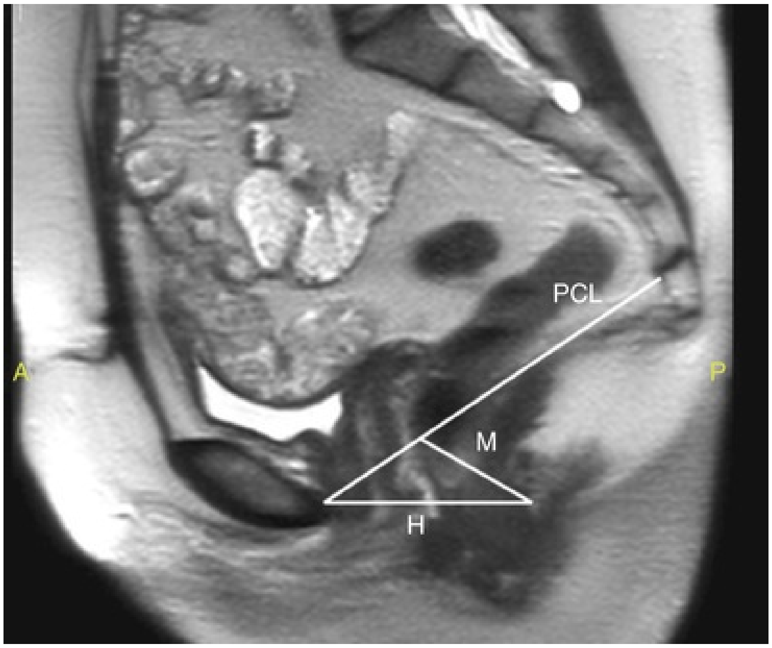

FIG. 108.25 Dynamic half-Fourier acquisition single-shot turbo spin-echo sequence T2-weighted magnetic resonance image in a patient with minor prolapse. H-line measures levator hiatus, M-line measures descent of the levator plate, and PCL measures pubococcygeus line. *A,* Anterior; *P,* posterior.

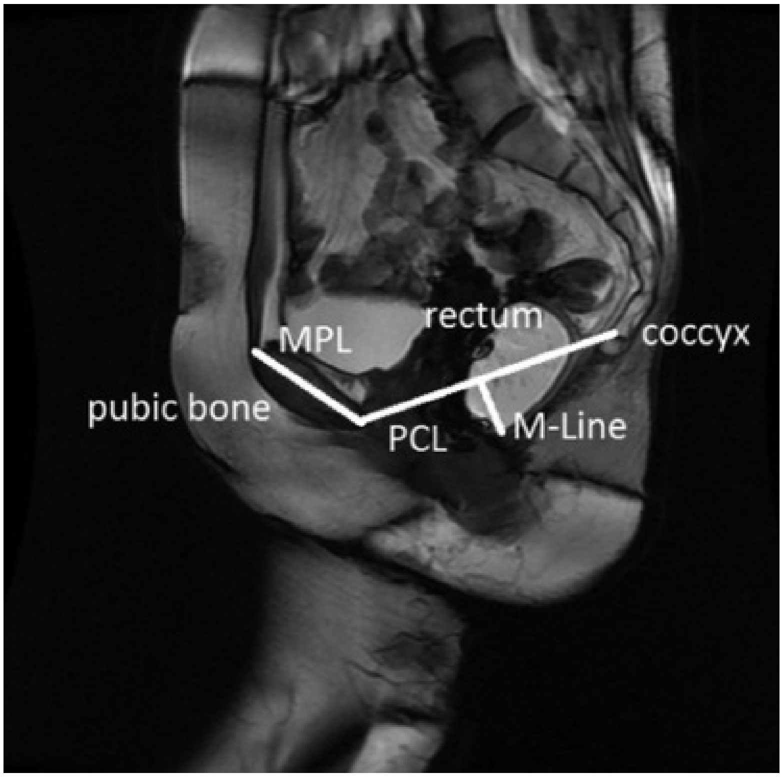

FIG. 108.26 Prolapse classification in magnetic resonance image. *1,* Perineal line; *2,* midpubic line; *3,* H-line; *4,* pubococcygeus line. (From Onal S, Lai-Yen S, Bao P, Weitzenfeld A: Image-based measurements for evaluation of pelvic organ prolapse. *J Biomed Eng* 6(1):45–55, 2013.)

Fluoroscopy

Fluoroscopy is often used to obtain real-time imaging, especially to capture dynamics pictures of the bladder and urethra during voiding. A low-dose radiographic beam passes to an image intensifier (Raman and Boyadzhyan, 2008b) and high-resolution monitor to create the image. **A cystogram is performed by taking static images of the bladder in different views after contrast is instilled and followed with a postdrainage picture. This modality may be used to diagnose bladder perforations, intravesical filling defects, and diverticula.** Low-pressure fistulae of the bladder may also be visualized (Fig. 108.27).

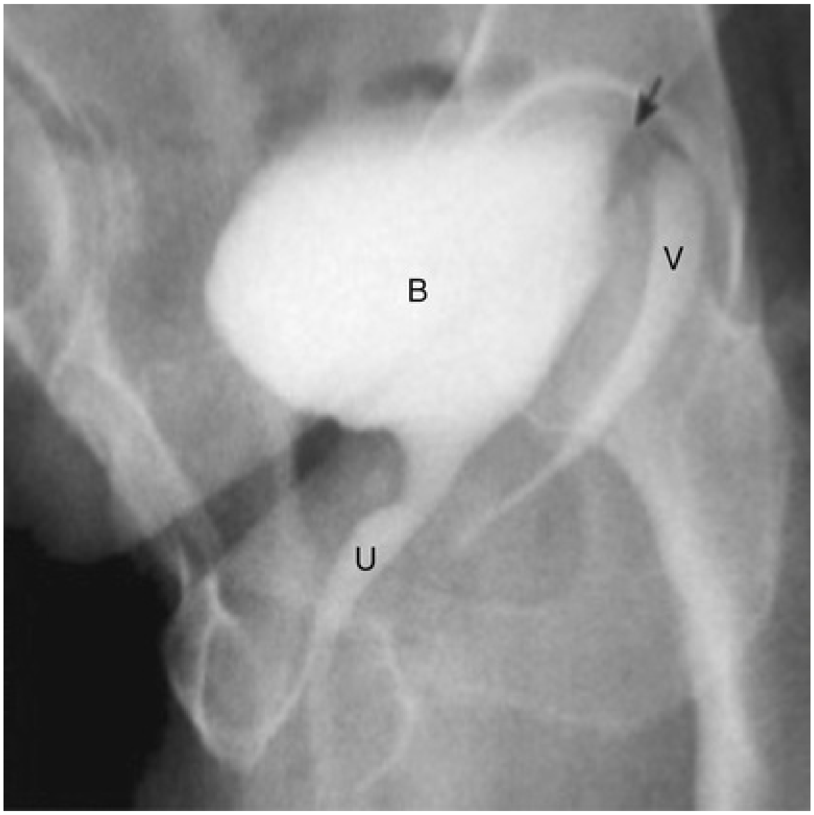

FIG. 108.27 Cystogram of vesicovaginal fistula. *B,* bladder; *U,* urethra; *V,* vagina.

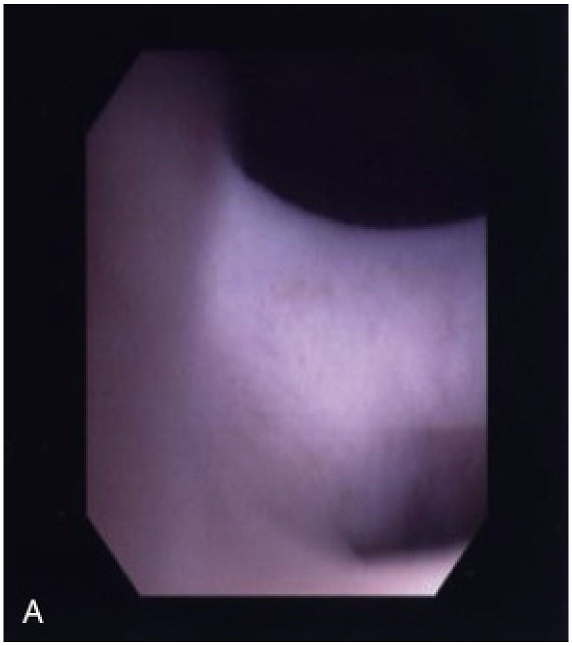
A voiding cystourethrogram (VCUG) takes dynamic pictures during filling and voiding, postcontrast instillation into the bladder, and after subsequent catheter removal. This modality may be used concurrently with urodynamics to dynamically correlate with radiographic findings. VCUG imaging is especially helpful to evaluate the urethra and bladder outlet anatomy during voiding. **Vesicoureteral reflux, vesical fistulas, urethral obstruction, urethral diverticulae, and high-grade cystoceles may also be diagnosed with a VCUG.**

Endoscopic Anatomy

The normal urethra, typically 14 to 20 Fr in caliber (Keegan et al., 2008), may be evaluated with a rigid or flexible cystoscope. Translabial, transrectal, and transvaginal ultrasound has been used for diagnosis of urethral injury and stricture. The entire urethra, external sphincter, and bladder neck should be visualized in a retrograde and antegrade fashion, with a 0 or 30-degree lens, while irrigation is flowing to distend the urethra. The urethra is closely evaluated in women with recurrent urinary tract infections, dysuria, or obstruction. Cystoscopy is valuable for visualization of foreign bodies, stones, and the ostia of a urethral diverticulum.

The entire bladder mucosa, ureteral orifices, and trigone may be visualized with an additional 70-degree lens. At the trigone and base of the bladder, premenopausal women exhibit normal signs of squamous metaplasia (Clouston and Lawrentschuk, 2013). This is nonkeratinizing metaplasia or vaginal metaplasia that is hormonally responsive and is a normal variant. Cystoscopy is additionally useful for identifying tumors, masses, foreign bodies, fistula openings, trabeculation, or stones (Fig. 108.28A and B).



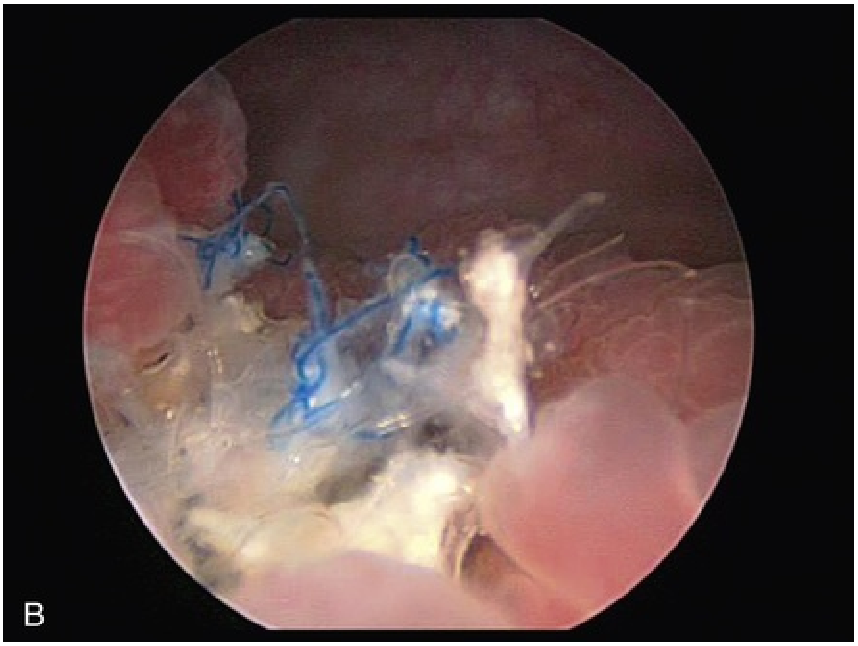


FIG. 108.28 Cystoscopic images. (A) Proximal urethral fistula. (B) Retropubic mid-urethral sling erosion.

Key Points: Radiographic and Endoscopic Anatomy

- Translabial ultrasound is useful for visualization of transvaginal mesh, urethral bulking agents, and urethral implants.
- MRI is the most comprehensive and conclusive imaging modality available to image the female pelvis without the use of radiation.
- T2-weighted MRI is the best imaging technique to visualize and localize urethral diverticula and to differentiate them from other benign vaginal masses.

Surgical, Radiographic, and Endoscopic Anatomy of the Male Pelvis

---

Jen-Jane Liu MD, Bryan Foster MD, Christopher L. Amling MD, FACS

Bony Pelvis

The bony pelvis consists of the sacrum posteriorly and the paired innominate bones anteriorly and laterally. **The innominate bones consist of three fused bones: the ilium, ischium, and pubis.** This fusion is centered at the acetabulum with the ilium forming the upper acetabulum, the ischium forming the posterior inferior acetabulum, and the pubis forming the anterior acetabulum. The innominate bones ("hip bones") articulate with the sacrum posteriorly at the sacroiliac (SI) joint and come together anteriorly to form a cartilaginous joint at the pubic symphysis. The sacrum is further fixed to the hip bones by two very strong ligaments, the sacrotuberous and sacrospinous ligaments. The more posterior sacrotuberous ligament extends from the sacrum/coccyx to the ischial tuberosity, and the more anterior sacrospinous ligament connects the sacrum/coccyx to the ischial spine (Fig. 109.1). These ligaments stabilize the sacrum, allowing only limited upward movement and thus providing resilience to the SI joint when the vertebral column sustains sudden weight increases. These bridging ligaments also create foramina, the sacrotuberous ligament the common sciatic foramen and the sacrospinous ligament bisects the sciatic foramen and forms the greater and lesser sciatic foramina. In the standing position, the pelvis curves obliquely backward relative to the trunk and abdominal cavity. The whole pelvis is tilted forward, with the plane of the pelvic brim making an angle 50 to 60 degrees with the horizontal.

The pelvis is classically divided into the greater (false) pelvis, formed by the iliac fossa with the cephalad extent being the iliac crest and the lesser (true) pelvis, which contains the urogenital organs. **The true and false pelvises are separated by the arcuate line, which extends from the sacral promontory posteriorly to the pubis anteriorly, where it becomes continuous with the pectineal line of the pubis**. The pelvic outlet or inferior pelvic aperture is an incomplete bony line roughly forming a circle with its boundaries being the lower aspect of the symphysis pubis, ischiopubic rami, ischial tuberosities, sacrotuberous ligaments, and coccyx. Bony landmarks commonly encountered during urologic surgery include the pubic arch and pubic symphysis, the ischial tuberosities, and the bony iliac crest, which lies at the level of the L4 vertebra and can be easily palpated as it extends posteriorly from the anterior superior iliac spine. During inguinal hernia repair or urethral suspension procedures, sutures are often placed in the Cooper (pectineal) ligament, which overlies the pectineal line of the pubis. Pelvic x-rays and fluoroscopy show pelvic bony landmarks with high resolution and detail (Fig. 109.2A and B).

Lower Abdominal Wall

Skin and Subcutaneous Fascia

The umbilicus indicates the level of the T10 dermatome and is typically at the level of the L3 vertebrae, although its position varies with the amount of fat in the subcutaneous tissue of the abdominal wall. In individuals with good muscle definition, curved skin grooves called the *semilunar lines* demarcate the lateral borders of the rectus abdominis and rectus sheath. These semilunar lines extend from the inferior costal margin near the ninth costal cartilages to the pubic tubercles bilaterally. Three transverse skin grooves may overlie the tendinous intersections of the rectus abdominis muscle. A skin crease, the inguinal groove, indicates the site of the inguinal ligament, and the groove located just inferior and parallel to this ligament marks the division between the anterior abdominal wall and the thigh.

The subcutaneous tissue of the lower abdominal wall is composed of two layers: a superficial fatty layer (Camper fascia) and a deep membranous layer (Scarpa fascia). The superficial circumflex iliac, external pudendal, and superficial inferior epigastric vessels branch from the femoral vessels and run in the loose fatty layer of Camper fascia. The superficial inferior epigastric vessels may be encountered during inguinal incisions or placement of laparoscopic trocars. **Scarpa fascia forms a distinct layer deep to Camper fascia but blends superficially and laterally with Camper fascia. Inferiorly, Scarpa fascia fuses with the deep fascia of the thigh (fascia lata) along a line approximately 1 cm inferior and parallel to the inguinal ligament. Medially, it is continuous with Colles fascia of the perineum, which fuses to the ischiopubic rami laterally and the posterior edge of the perineal membrane**. **Colles fascia is also continuous with dartos fascia of the penis and scrotum** (Fig. 109.3). These fascial layers limit of the spread of necrotizing soft-tissue infections of the scrotum and the extent of urinary extravasation and/or bleeding after anterior urethral injury. After anterior urethral injury, blood can accumulate in the scrotum and penis deep to the dartos fascia. This hematoma is limited by the fusions of Colles fascia to the ischiopubic rami laterally, resulting in a “butterfly” hematoma. Although these fascia also prevent bleeding, infection, or urinary extravasation from extending down the leg or into the buttock, they do not limit spread cephalad in the space deep to Scarpa fascia, thus allowing extension up the abdominal wall around the flank to the back.

Musculature

The lower abdominal wall musculature lies deep to Scarpa fascia. From the origins of the external oblique, internal oblique, and transversus abdominis muscles, these muscles terminate medially on the anterior abdominal wall as aponeurotic sheets that fuse in the midline at the linea alba, a convenient landmark for lower abdominal incisions. These three muscles also form the rectus sheath. Superior to the arcuate line, about one-third of the distance from the umbilicus to the pubic crest, the rectus abdominis is enveloped by the anterior and posterior rectus sheath. At this level, the anterior rectus sheath is formed by the aponeurosis of the external oblique muscle and a portion of the internal oblique muscle. The posterior sheath is derived from the remaining internal oblique aponeurosis and the transverses abdominis aponeurosis. **Below the arcuate line, all aponeurotic layers pass anterior to the rectus abdominis so that at this lower level, the rectus abdominis is covered only by the transversalis fascia and peritoneum posteriorly** (Fig. 109.4).

The rectus abdominis attaches to the pubis medial to the pubic tubercle and extends to its insertion on the xiphoid process and adjacent costal cartilages. The muscle fibers of the rectus do not run the length of the muscle. Rather, they run between three or more tendinous intersections, which are typically located at the level of the xiphoid process of the sternum, the umbilicus, and a level halfway between these points. Each intersection is firmly attached to the anterior layer of the rectus sheath. Thus the rectus abdominis muscle can be divided transversely without significant retraction. Its nerve supply is derived from thoracic segmental nerves that entered laterally. Division of these nerves during a paramedian incision lateral to the rectus may cause atrophy of the rectus and predispose to ventral hernia. The pyramidalis muscle is a small triangular muscle (absent in about 20% of people) that lies anterior to the rectus muscle but within its sheath. It arises from the pubic crest and inserts into the linea alba, which tenses with contraction (Fig. 109.5).

Inguinal Canal

In adults, the inguinal canal is an inferior-medially directed oblique passage (approximately 4 cm long) that runs through the inferior part of the anterior abdominal wall. **The inguinal canal transmits the spermatic cord and the ilioinguinal nerve. It has a deep (internal) and superficial (external) inguinal**

ring. The deep ring serves as the internal entrance to the inguinal canal and is an evagination of the transversalis fascia superior to the inguinal ligament and lateral to the inferior epigastric vessels (Fig. 109.5B and C). The external inguinal ring is a slitlike opening in the aponeurosis of the external oblique, superior-lateral to the pubic tubercle, serving as the exit from the inguinal canal. The internal inguinal ring lies midway between the anterior superior iliac spine and the pubic tubercle, above the inguinal ligament and 4 cm lateral to the external ring.

The anterior wall of the inguinal canal is formed by the external oblique aponeurosis throughout the length of the canal but is reinforced laterally by the lower most fibers of the internal oblique muscle. The posterior wall is formed by transversalis fascia with the posterior medial part of the canal reinforced by the merging of the internal oblique and transversus abdominis aponeurosis into a common tendon, the inguinal falx (conjoint tendon). This tendon reinforces the posterior wall of the inguinal canal at the external ring (Fig. 109.6). The roof of the inguinal canal is also formed by internal oblique and transversus abdominis fibers, which arch over the canal before fusing at the conjoint tendon. The floor of the canal is formed laterally by the iliopubic tract, centrally by the superior surface of the “gutter-like” inguinal ligament, and medially by the lacunar ligament. With contraction of the internal oblique and transversus muscles, the roof of the canal closes against the floor, preventing herniation of intra-abdominal contents into the canal. Hernias into the canal may occur medial (direct) or lateral (indirect) to the inferior epigastric vessels (see Fig. 109.5B and C).

Internal Peritoneal Elevations

The internal surface of the lower abdominal wall is covered with transversalis fascia, a variable amount of extraperitoneal fat, and parietal peritoneum. Below the umbilicus, the abdominal wall exhibits several peritoneal folds, some of which contain remnants of fetal vessels. These folds are identified easily during peritoneal laparoscopic/robotic surgery (Fig. 109.7). The median umbilical fold, extending from the apex of the bladder to the umbilicus, covers the median umbilical ligament, the remnant of the urachus that joined the apex of the fetal bladder to the umbilicus. The two medial umbilical folds lateral to the median umbilical fold cover the medial umbilical ligaments formed by the obliterated umbilical arteries. These ligaments, which can be traced to their origin from the internal iliac artery, serve as important landmarks for the surgeon. During transperitoneal laparoscopic surgery, access to the obturator fossa and space of Retzius is gained by incising the peritoneum lateral to these ligaments. The two lateral umbilical folds, which lie lateral to the medial umbilical folds, cover the inferior epigastric vessels as they ascend in the abdominal wall to supply the rectus abdominis muscle.

FIG. 109.7 Internal view of peritoneal elevations.

Key Points: Pelvis

- The bony pelvis consists of three fused bones: the ilium, ischium, and pubis.
- The true and false pelvises are separated by the arcuate line.
- The inguinal canal transmits the spermatic cord and the ilioinguinal nerve.

Soft Tissues of the Pelvis

Musculature

The lateral pelvic sidewalls are covered and padded by the obturator internus muscles, which exit the pelvis through the lesser sciatic foramen to insert on the femur. The medial surface of these muscles is covered by obturator fascia, which is thickened centrally as a tendinous arch extending from the ischial spine to the lower half of the pubis. **This tendinous arc of the levator ani serves as the origin of the muscular attachments of the bowl-shaped pelvic diaphragm, which consists of the levator ani and coccygeus muscles** (Fig. 109.8). The most posterior muscle of this pelvic diaphragm and the smallest part of it, the coccygeus muscle, extends from the ischial spine to the inferior end of the sacrum and coccyx. In addition to providing support for pelvic viscera, this muscle also flexes the coccyx. The bulk of the pelvic diaphragm is composed of the three muscular parts of the levator ani, the puborectalis, pubococcygeus, and iliococcygeus muscles. The most anterior of these, the puborectalis, forms a U-shaped muscular sling that passes posterior to the anorectal junction, playing a major role in maintaining fecal continence.

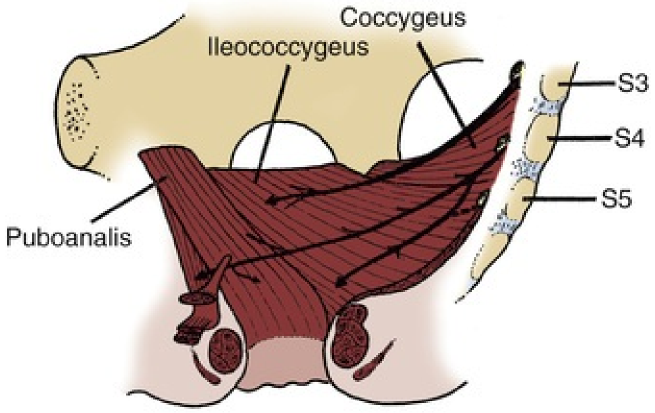

FIG. 109.8 Muscles of the pelvic floor. (From Lawson JO: Pelvic anatomy. I. Pelvic floor muscles. *Ann R Coll Surg Engl* 54:244–252, 1974.)

The levator ani muscles are under somatic control, providing a dynamic pelvic floor that is tonically contracted to support the pelvic viscera and to maintain urinary and fecal continence. They contain both type I (slow-twitch) and type II (fast-twitch) fibers (Gosling et al., 1981). Together, the muscles of the levator ani relax to allow defecation and urination and then contract to raise the pelvic floor. Further contraction occurs with Valsalva maneuvers to resist the increased intra-abdominal pressure that would otherwise force the abdominopelvic contents through the pelvic outlet. Kegel exercises to regain or maintain urinary continence after pelvic surgery are focused on increasing the tonic contraction of these muscles.

Pelvic Fascia

The pelvic fascia is connective tissue that is a continuation of retroperitoneal fascia and fascia that lies between the muscular and peritoneum layers of the lower abdominal wall. It can be divided into the parietal pelvic fascia, which forms the coverings of the pelvic muscles, and the visceral pelvic fascia, which forms a covering of the pelvic organs and their neurovascular supply. The parietal pelvic fascia is a membranous layer of variable thickness that lines the pelvic aspect of muscles forming the walls and floor of the pelvis. This layer is continuous superiorly with the transversalis fascia of the abdominal wall. It is fixed to the arcuate line of the pelvis, Cooper ligament, the sacrospinous ligament, the ischial spine, and tendinous arch of the levator ani. On the superomedial aspect of the upper parietal fascia over the levator ani, a thick white band of condensed connective tissue extends from the puboprostatic ligament to the superior margin of the ischial spine. This arcus tendineus fascia forms a junction between parietal and visceral fascia and provides attachment for the condensations of visceral fascia that provide support to the urethra and bladder. The visceral pelvic fascia directly ensheaths the pelvic organs, forming the adventitial layer of each. The lateral attachments of the pelvic organs to the pelvic sidewalls are referred to as the endopelvic fascia. These connections allow a conduit for conducting neurovascular structures from the pelvic sidewall to the organs and provide attachments that hold pelvic organs in place. The loose connective tissue associated with these mesenteries extend to the midline, separating the bladder, prostate, and seminal vesicles from the rectum. All pelvic vascular structures and some pelvic nerves travel in this fascial layer.

Perineum

Perineal Fascia

The perineal fascia consists of a superficial fatty layer and a deep membranous layer (Colles fascia). The subcutaneous layer is greatly diminished in males, being replaced altogether in the penis and scrotum with smooth (dartos) muscle. It is continuous between the penis or scrotum and thighs with the subcutaneous fatty layer of the abdominal wall. The membranous layer of the superficial perineal fascia (Colles fascia) is attached posteriorly to the posterior margin of the perineal membrane and laterally to the fascia lata of the medial thigh. It is continuous anteriorly with the dartos fascia of the penis and scrotum and the membranous layer of subcutaneous tissue of the abdomen (Scarpa fascia). **The urogenital triangle is enclosed by a thin sheet of tough, deep fascia referred to as the perineal membrane. The perineal membrane has a triangular shape and spans between the right and left pubic arch (inferior ischiopubic rami) extending from the pubis to the ischial tuberosities** (Fig. 109.9). It is perforated by the urethra. The anterior aspect of the perineal membrane supports the urethral sphincter, and the external genitalia attach to its inferior surface. The superficial and deep transverse perineal muscles run along its posterior edge to converge in the midline at the perineal body. **The perineal body is not a structure itself but instead an aggregation of fibromuscular tissue located in the midline at the junction between the urogenital and anal triangles.** Anteriorly, the perineal body blends with the posterior border of the perineal membrane and superiorly with the rectovesical septum, which is contiguous with Denonvilliers fascia. The perineal body is the focal point of pelvic support with nearly every pelvic muscle and fascia inserting into it. Disruption or injury to the perineal body during perineal prostatectomy risks postoperative urinary, and possibly fecal, incontinence.

FIG. 109.9 Muscles and fascia of the male perineum. (Modified from Standring S: *Gray's anatomy: the anatomical basis of clinical practice,* ed 41, Philadelphia, 2016, Elsevier, Fig. 73-12.)

The term "perineum" is used to refer to an external surface area (perineal region) and shallow compartment of the body limited superiorly by the pelvic diaphragm, the bowl-shaped fibromuscular layer formed by the levator ani and coccygeus muscles. The osseofibrous structures marking the boundaries of the perineal compartment include the symphysis pubis anteriorly, the ischiopubic rami anterolaterally, ischial tuberosities laterally, sacrotuberous ligaments posterolaterally, and the coccyx posteriorly. By convention, the perineum is divided into two triangles (anal and urogenital triangle) by a transverse line joining the anterior ends of the ischial tuberosities) (Fig. 109.9).

Anal Triangle

The anal triangle contains the anal canal and its sphincters and the ischiorectal fossa and its contained nerves and vessels. It is lined by superficial and deep fascia. The subcutaneous fatty tissue of the anal triangle surrounds the anus and is continuous with the subcutaneous fat of the urogenital triangle, buttocks, and thigh. The ischiorectal fossa, bounded by the levator ani medially and the obturator internus and sacrotuberous ligament laterally, is filled with fat and extends anteriorly to a recess above the urogenital diaphragm. It also extends posteriorly into the pelvis through the sciatic foramina. This continuity with the pelvis allows extension of perirectal infections between the perineum and pelvic cavity.

The anal canal begins where the ampulla of the rectum abruptly narrows at the level of the U-shaped sling formed by the puborectalis muscle. The anal canal is surrounded by the internal and external anal sphincters. The internal sphincter is an involuntary sphincter surrounding the upper two-thirds of the anal canal. It represents a thickening of the inner circular smooth muscle layer of the rectum. Its tonic contraction is maintained by sympathetic nerves and lessened by parasympathetic nerves, allowing it to expand passively during defecation. The external anal sphincter is a large voluntary sphincter forming bands of muscle around the inferior two-thirds of the anal canal and has subcutaneous, superficial, and deep parts. The subcutaneous portion attaches to the perineal body by collagenous and muscular fibers referred to as the central tendon of the perineum. The superficial part is attached to the perineal body and coccyx, and the deep portion blends with the puborectalis sling of the levator ani. Disruption of this muscular band results in fecal incontinence. During perineal prostatectomy, the prostate can be approached either by dividing the central tendon and sphincteric attachments to the perineum, leaving the external sphincter on the rectum (Young procedure), or by going under the external sphincter along the anterior rectal wall (Belt procedure).

Urogenital Triangle

The male urogenital triangle is enclosed by the scrotum anteriorly and the perineal body posteriorly. The skin and subcutaneous fat overlie Colles fascia, which attaches posteriorly to the perineal membrane (with the perineal body in the center), forming a superficial pouch. Deep to this pouch lies the root of the penis, with the paired corpora cavernosa attaching to the inferior ischiopubic rami and perineal membrane and the corpus spongiosum of the bulbar urethra attaching to the perineal membrane. The bulb of the penis is surrounded by the bulbospongiosus muscle, and the corpora cavernosa are surrounded by the ischiocavernosus muscles. Contraction of these muscles compresses the corpora cavernosa during penile erection.

The internal pudendal artery and its branches supply the perineum. After branching from the internal iliac artery, the internal pudendal artery travels through the lesser sciatic foramen, medial to the obturator internus in Alcock canal. It sends branches to the anus and then travels through Colles fascia into the superficial pouch of the urogenital triangle and posterior scrotum before terminating as the dorsal artery of the penis (Figs. 109.10 and 109.11).

The internal pudendal veins anastomose with the dorsal venous complex in the pelvis via a plexus on the lateral surface of the prostate that can cause bleeding during prostatic dissection. The inferior rectal veins arise from the internal pudendal vein and anastomose with the middle and superior rectal veins, which eventually drain to the inferior mesenteric vein. Obstruction of either the portal circulation from the inferior mesenteric vein or the systemic circulation from the inferior rectal veins can result in dilation of the venous plexus and hemorrhoid formation.

The pudendal nerve travels with the internal pudendal vessels in Alcock canal to innervate the perineum. Anteriorly, its first branch is the dorsal nerve of the penis, followed by branches that supply the ischiocavernosus and bulbospongiosus muscles, as well as sensory nerves to the posterior scrotum (Fig. 109.11). Perineal branches supply the striated urethral sphincter and levator ani. Posteriorly, the rectal branches supply the external sphincter and provide sensation to the perianal skin.

Key Points: Perineum

- The perineum is bordered by the symphysis pubis, ischiopubic rami, ischial tuberosities, sacrotuberous ligaments, and coccyx.
- The perineum is composed of two triangles: the urogenital triangle and anal triangle.
- The blood supply to the perineum is the internal pudendal artery and its branches, and its innervation is the pudendal nerve.

Pelvic Circulation

Arterial Supply

At the aortic bifurcation the middle sacral artery travels to the anterior sacrum, where it supplies the rectum and sacral foramina (Table 109.1). It may be encountered during dissection of the presacral space. **The common iliac arteries course anteriorly to the common iliac veins and split into an external and internal branch at the level of the sacroiliac joint.** The external iliac artery sits anterolateral to the vein and on top of the iliopsoas muscle. It eventually crosses under the inguinal ligament, where it becomes the femoral artery. Distal branches of the external iliac artery may be encountered during pelvic lymph node dissection, including the inferior epigastric artery (which leaves the artery proximal to the inguinal ligament and travels to the rectus muscle) and the deep circumflex iliac and pubic branches. The cremasteric artery also branches from the inferior epigastric artery, where it travels with the spermatic cord. Accessory obturator vessels may be encountered during pelvic lymph node dissection as they branch from the inferior epigastric vessels and travel into the obturator fossa.

TABLE 109.1

Arteries of the Pelvis

ARTERY NAME	ORIGIN	SUPPLIES
Middle sacral	Aorta	Sacral nerves and sacrum
EXTERNAL ILIAC BRANCHES		
Inferior epigastric	External iliac	Rectus abdominis muscle and overlying skin and fascia
Deep circumflex iliac	Inferior epigastric	Inguinal ligament and surrounding structures laterally
Pubic	Inferior epigastric	Inguinal ligament and surrounding structures medially
Cremasteric	Inferior epigastric	Vas deferens and testis
INTERNAL ILIAC BRANCHES		
Superior gluteal	Posterior	Gluteus muscles and overlying skin

	trunk	
Ascending lumbar	Posterior trunk	Psoas and quadratus lumborum muscles and adjacent structures
Lateral sacral	Posterior trunk	Sacral nerves and sacrum
Superior vesical	Anterior trunk	Bladder, ureter, vas deferens, and seminal vesicle
Middle rectal	Anterior trunk	Rectum, ureter, and bladder
Inferior vesical	Anterior trunk	Bladder, seminal vesicle, prostate, ureter, and the neurovascular bundle
Internal pudendal	Anterior trunk	Rectum, perineum, and external genitalia
Obturator	Anterior trunk	Adductor muscles of the leg and overlying skin
Inferior gluteal	Anterior trunk	Gluteus muscles and overlying skin

The internal iliac (hypogastric) artery travels posteriorly after branching from the common iliac artery to supply the deep pelvis. It is divided into an anterior and posterior trunk. The anterior trunk gives off several branches: the umbilical artery, the obturator artery, the middle rectal and inferior vesical artery, the internal pudendal artery, and then the inferior gluteal.

The umbilical artery is typically obliterated after its take off from the internal iliac artery and becomes the medial umbilical ligament along the anterior abdominal wall (see Fig. 109.7), which is an important landmark in pelvic surgery when entering the extraperitoneal space. **The superior vesical artery arises from the umbilical artery proximally and supplies the bladder along with the inferior vesical artery.** The artery of the vas deferens also comes from a branch of the umbilical artery and joins the cremasteric and testicular arteries in the spermatic cord, providing an additional blood supply to the testicle. The obturator artery supplies the adductor muscles of the thigh and travels through the obturator foramen and can be encountered deep and medial to the obturator nerve, particularly during pelvic lymph node dissection (Fig. 109.12).

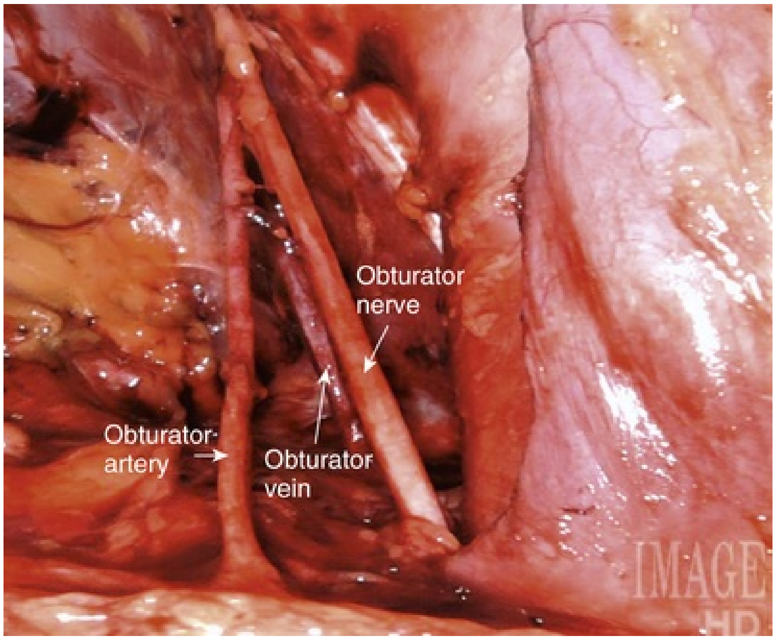

FIG. 109.12 Intraoperative photo of obturator fossa after lymph node dissection.

Venous Supply

The pelvis has a rich venous network. The external and internal iliac veins course inferior and medial to their corresponding arteries and join together behind the internal iliac artery, where they can be injured during pelvic lymph node dissection, resulting in significant bleeding. An accessory obturator vein may drain into the external iliac vein, which may also be encountered during lymph node dissection.

The dorsal venous complex drains the penis and enters the pelvis beneath the pubic symphysis in the midline anterior to the striated sphincter and then divides into a central superficial branch and a deeper plexus (Fig. 109.13). It is important to control when performing prostatectomy to minimize bleeding; however, this maneuver can damage the sphincter, particularly laterally. The prostatic venous plexus (Santorini plexus) drains the prostate and part of the rectum and may be encountered when entering the lateral prostatic fascia during radical prostatectomy. It eventually drains into the internal iliac vein, along with several inferior vesical veins.

Pelvic Lymphatics

The drainage from the pelvic viscera includes the iliac lymph nodes and its tributaries. There is frequent cross drainage between the right and left side of the pelvis. The external iliac lymph nodes extend from the top of the external iliac artery distally to just over the pelvic brim. They drain the anterior abdominal wall, urachus, and bladder. The most distal portion of the lymph node packet as the external iliac artery exits the femoral canal is referred to as the node of Cloquet and serves as the distal limit of pelvic lymph node dissection. The internal iliac lymph nodes receive drainage from the prostate and bladder. The presacral and obturator lymph nodes also drain into the internal iliac lymph node chain. The lymphatic drainage for the external genitalia is the inguinal lymph nodes, which then drain into the iliac lymph nodes.

Pelvic Innervation

The sensation to the pelvis and genitalia comes from the lumbosacral plexus. The iliohypogastric nerve originates from L1 to supply the anterior abdominal wall. The ilioinguinal nerve also originates from L1 and travels through the inguinal canal, providing sensation to the anterior scrotal skin. The genitofemoral nerve arises from L1 and L2 and splits into genital and femoral branches. It travels over the anterior surface of the psoas muscle. The genital branch travels through the inguinal canal to supply the cremaster muscle and anterior scrotum. The femoral branch provides sensation from the anterior thigh (Table 109.2).

TABLE 109.2

Somatic and Autonomic Nerves of the Pelvis

NERVE	SOURCE	SUPPLIES	ANATOMIC COURSE

erigentes		the sacral cord that supply the pelvic viscera	and rectum

Motor Nerves

The femoral nerve comprises branches from L2-L4 and contributes sensation to the anterior thigh and motor innervation to the extensors of the thigh. It travels deep within the psoas muscle but can be injured during psoas hitch, by pressure from retractor blades during laparotomy, or during inguinal lymph node dissection. The obturator nerve also originates from L2-L4 and is first apparent between the internal iliac vessels and the pelvic side wall at the bifurcation of the common iliac vessels; it travels anteriorly through the obturator canal (Fig. 109.14). Damage to this structure can occur during pelvic lymph node dissection, resulting in difficulty with adduction of the thigh.

FIG. 109.14 (A and B) Innervation of the pelvis. (Modified from Standring S: *Gray's anatomy: the anatomical basis of clinical practice,* ed 41, Philadelphia, 2016, Elsevier, 2016.)

The sacral plexus is formed by the lumbosacral trunk (L4, L5) and the sacral segmental nerves and is located between the internal iliac vessels and the piriformis muscle. It then travels through the greater sciatic foramen to innervate the lower leg and posterior thigh. The sensory branches to the pelvis are listed in Table 109.2.

Autonomic Nerves of the Pelvis

The sympathetic nerves of the pelvis originate in the lateral horn of the thoracic and lumbar spinal cord (T10-L2) and then travel to the pelvis via the superior hypogastric plexus and the sympathetic chain (Fig. 109.15). The hypogastric plexus is a continuation of nerve fibers from the celiac plexus and lumbar sympathetic nerves. It eventually becomes two discrete hypogastric nerves that travel anterior to the aorta and medial to the internal iliac artery into the pelvis beneath the endopelvic fascia. The sympathetic trunks are located lateral to the vertebral bodies and continue behind the iliac vessels to terminate in front of the coccyx.

FIG. 109.15 Sympathetic and parasympathetic contributions to the pelvic autonomic nervous plexus.

Parasympathetic nerves in the pelvis come from the lateral horns of the sacral spinal cord (S2-S4) and join the sympathetic hypogastric plexus to form the pelvic plexus. The pelvic plexus is on either side of the rectum, centered around the seminal vesicles (Fig. 109.16), innervating the rectum, bladder neck, and distal ureter. Distally, the pelvic plexus innervates the prostate and continues as cavernosal nerves that run posterolateral to the prostate on the surface of the rectum outside of Denonvillier fascia. Prostatic arteries and veins travel with the nerve fibers forming a neurovascular bundle. **The neurovascular bundle continues between the 5 and 7 o'clock position at the apex of the prostate and then sends branches to the striated sphincter and corpora cavernosa to supply erectile tissue.** Damage to the neurovascular bundle or pelvic plexus during prostatectomy or rectal resection results in erectile dysfunction.

Key Points: Pelvic Circulation and Innervation

- The vascular supply to the pelvis derives from the common iliac vessels and its branches, with the deep pelvis supplied by the internal iliac vessels.
- There is frequent cross-drainage between lymphatics to both sides of the pelvis.
- Prostatic arteries, veins, and the cavernosal nerves form the neurovascular bundle, which supplies erectile tissue.

Pelvic Viscera

Rectum

The rectum starts at the level of S3 and follows the curvature of the sacrum through the pelvic floor and terminates in the perineum as the anus. The anterior portion of the rectum is covered with peritoneum distally up to the rectovesical pouch. Incision of this peritoneum allows access to the seminal vesicles posterior to the bladder as is commonly performed in the “posterior approach” to robotic prostatectomy. **Beyond the rectovesical pouch Denonvillier fascia separates the rectum from the prostate.** The rectal blood supply derives from the middle rectal artery (from the internal iliac artery) and the inferior rectal artery (from the internal pudendal artery). The pelvic plexus is located laterally and provides autonomic innervation. The most distal portion of the rectum is the ampulla, where the rectourethralis muscle can be found. This portion of the rectum is in proximity to the striated urethral sphincter and prostate and is the most common location of rectal injury at the time of prostatectomy.

Bladder

Covered by peritoneum superiorly, the bladder is mostly an extraperitoneal organ. The superior portion (e.g., dome) is in continuity with the urachus, which is a fibrous embryologic structure typically lined with epithelium, but obliterated. The urachus continues along the midline of the anterior abdominal wall and terminates in the umbilicus. The urachus can be a source of adenocarcinomas of the bladder, and persistent communication to the urinary tract may result in fistulas or cysts. **Anterior to the bladder is the space of Retzius, a potential extraperitoneal space that lies deep to the transversalis fascia and is often developed by surgical dissection to access the bladder or prostate**. Laterally, the bladder is surrounded by loose connective and adipose tissue, and posteriorly the ureters enter alongside the seminal vesicles and vasa deferentia (Fig. 109.17). Posterior to these structures lies the rectum. The adult bladder rests in the true pelvis. The bladder neck is firmly attached to the base of the prostate and the urothelium of the bladder is in continuity with the prostatic urethra. In infants, the bladder is intraabdominal and migrates into the true pelvis during puberty.

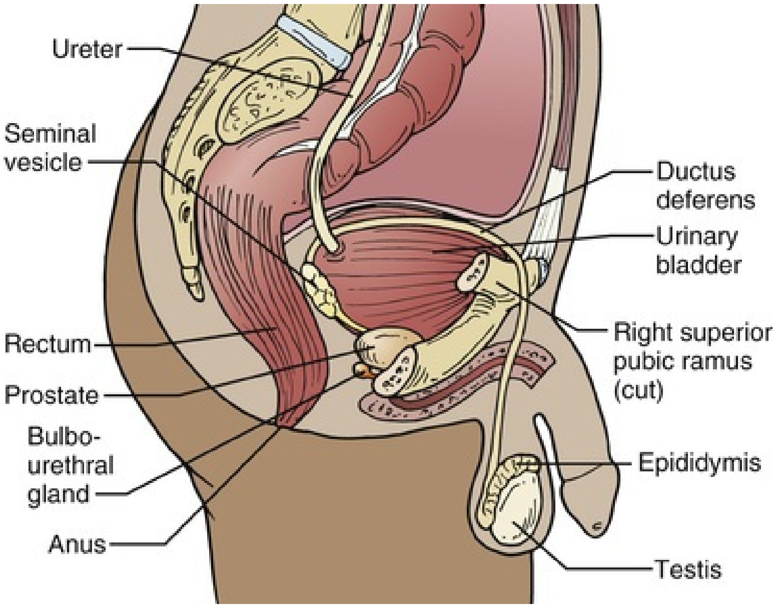

FIG. 109.17 Viscera of the male pelvis. (From Moses KP, Banks JC: Pelvic viscera. In Moses KP, Banks JC, Nava PB, Petersen DK, editors: *Atlas of clinical gross anatomy,* ed 2, Philadelphia, Elsevier, 2013, pp 460–477, Fig. 37.1.)

The bladder consists of several layers. The lining is a relatively impermeable transitional epithelium that is made up of several layers of cells with a superficial layer of umbrella cells. These cells are adherent to the connective tissue of the lamina propria and smooth muscle called the muscularis mucosae. Deep to this is the muscularis propria, which is composed of smooth muscle oriented in three separate layers (from inner to outer): longitudinal, circular, and longitudinal again. These fibers form a network that enables coordinated emptying of the bladder. These layers continue into the bladder neck, where the longitudinal fibers are continuous with the prostatic urethra. The circular fibers form the internal urethral sphincter (Brooks et al., 1998), which is an important component of continence in men. The role of this sphincter in continence is apparent post-prostatectomy, when these fibers may be damaged, resulting in urinary incontinence. The bladder neck is innervated by adrenergic nerve fibers, which enable it to close, allowing antegrade ejaculation. The trigone is the thickest portion of the detrusor muscle, and the outer longitudinal muscle fibers provide a strong muscular backing. Anteriorly, the longitudinal fibers are continuous with the puboprostatic ligaments.

Ureterovesical Junction

The ureters are encased by fibrous tissue (Waldeyer sheath) as they enter the trigone (Fig. 109.18). The entrance is cephalad and lateral, and the ureter travels 1.5 to 2 cm before reaching the ureteral orifice, which is located caudad and medial to its insertion into the bladder. The intramural ureter that travels through the detrusor is narrow and can be a site of obstruction in the setting of ureteral stones or significant bladder wall thickening. Because of the strong detrusor muscle backing, the intramural ureter is occluded during bladder filling, acting as a one-way valve for urine flow. Vesicoureteral reflux is thought to occur in part because of weak or shortened muscular backing of the intramural ureter. The entry point of the ureter is a point of weakness in the detrusor muscle and can form diverticula ("Hutch") from elevated intravesical pressures (Hutch et al., 1961). The superficial portion of the trigone is a triangular shape and formed from the joining of the longitudinal muscle fibers from the ureters, terminating at the verumontanum. The continuation of Waldeyer sheath and the detrusor muscle of the bladder form the outer layers of the trigone, anchoring the ureters to the bladder. The resultant fixation of the ureters to the detrusor allows for compression of the intramural ureter during bladder filling and helps prevent vesicoureteral reflux.

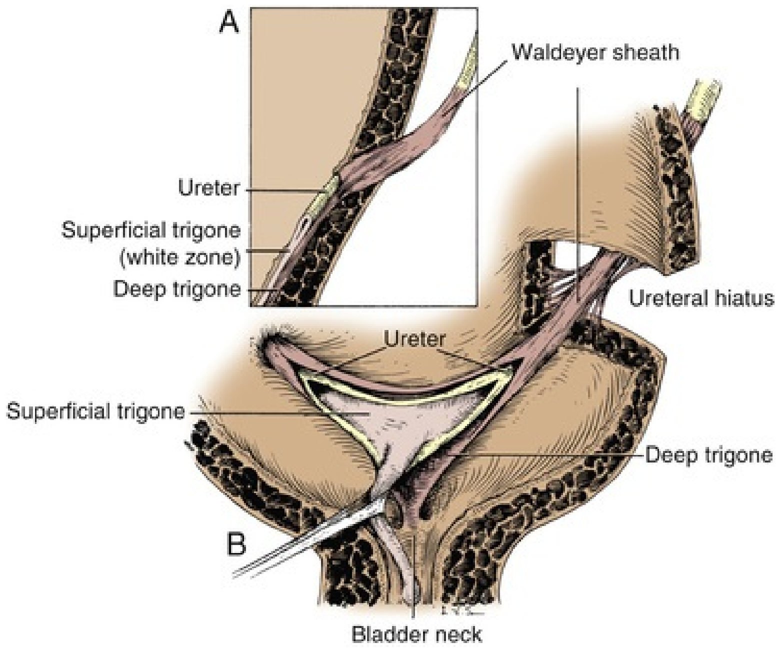

FIG. 109.18 Normal ureterovesical junction and trigone. (A) Section of the bladder wall perpendicular to the ureteral hiatus shows the oblique passage of the ureter through the detrusor and also shows the submucosal ureter with its detrusor backing. Waldeyer sheath surrounds the prevesical

ureter and extends inward to become the deep trigone. (B) Waldeyer sheath continues in the bladder as the deep trigone, which is fixed at the bladder neck. Smooth muscle of the ureter forms the superficial trigone and is anchored at the verumontanum. (From Tanagho EA, Pugh RCB: The anatomy and function of the ureterovesical junction. *Br J Urol* 35:151–165, 1963.)

Blood Supply and Lymphatic Drainage of the Bladder

In addition to the vesical branches, there are multiple other branches arising from the hypogastric artery that contribute to the vascular pedicles of the bladder, which can be found posterior and lateral to the bladder. The veins form a plexus within these pedicles and drain to the internal iliac vein. There are some lymph nodes in the perivesical space, but the lymphatics from the bladder start in the lamina propria layer and then drain largely to the external iliac lymph nodes, with some drainage to the internal iliac and obturator lymph nodes as well. **There is significant cross-drainage of lymphatics from the bladder, with drainage to both sides of the pelvis.**

Innervation of the Bladder

Efferent fibers come from the anterior portion of the pelvic plexus**. The bladder has a high density of parasympathetic cholinergic nerve endings, with relatively little sympathetic innervation.** There are also nonadrenergic, noncholinergic (NANC) fibers that innervate the bladder and are thought to use purines as neurotransmitters (Yoshida et al., 2001). Although their contribution to normal bladder contraction is relatively small, in pathological situations these receptors may be pharmacologic targets for intervention. The bladder neck has dense α1-receptors in males, enabling closure of the bladder neck for antegrade ejaculation and aiding continence. Nitric oxide synthase containing neurons can also be found in the bladder neck and trigone, which may promote relaxation during micturition. The afferent nerves from the bladder travel with the hypogastric plexus to reach the dorsal root ganglia in the spine.

Pelvic Ureter

The pelvic ureter begins as it crosses the common iliac artery. The proximity of the pelvic ureter to the iliac vessels results in a relative narrowing that can obstruct stone passage. The pelvic ureter can also become obstructed by extrinsic compression, such as by the gravid uterus or pathologically enlarged iliac lymphadenopathy. The structure of the ureter is reviewed in detail in Chapter 84. **After crossing the iliac vessels, the ureters travel laterally toward the pelvic side walls and then beneath the umbilical artery branch of the internal iliac artery. Then they turn medially behind the vas deferens to insert into the bladder.** The pelvic ureter is a retroperitoneal structure, although its peristalsis can be seen through the peritoneum in thin patients, particularly at the level of the iliac vessels.

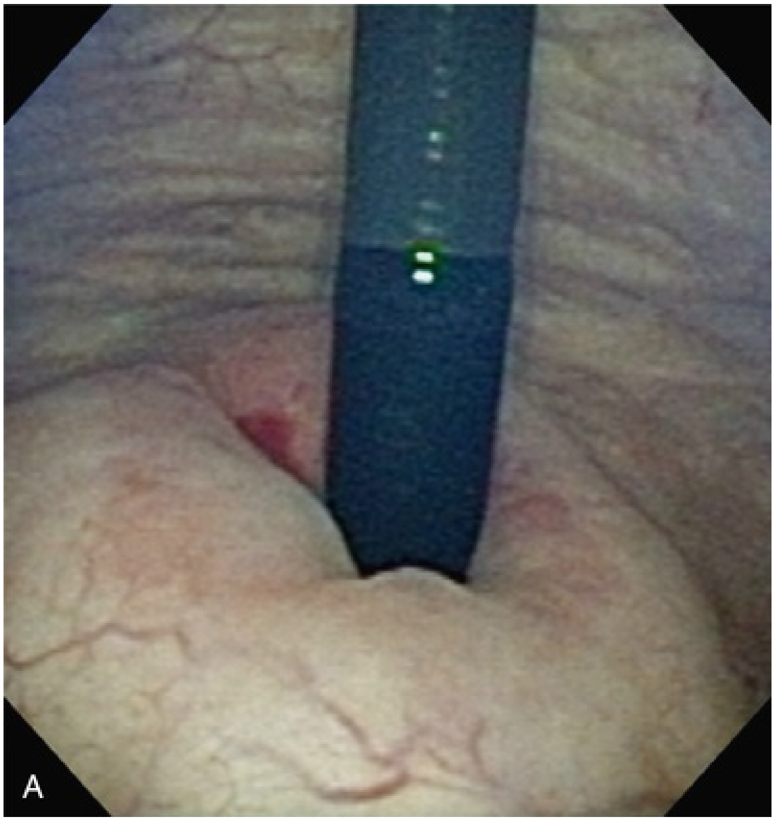
The blood supply to the pelvic ureter derives from the common iliac artery, and multiple branches from the internal iliac artery (see Table 109.2), which enter the ureter laterally. Leaving the lateral attachments when dissecting around the ureter prevents devascularization. There are intramural blood vessels in the adventitia of the ureter that allow for circumferential dissection if needed. However, the quality of the blood supply is variable, and the ureter can be prone to stricture formation after circumferential dissection or ligation. The lymphatics of the ureter drain to the common, external, and internal iliac lymph nodes.

Key Points: Pelvic Viscera

- The rectum is separated from the bladder by a fascial layer (Denonvillier).
- The bladder is mostly extraperitoneal except for the dome.
- The anterior extraperitoneal space (Retzius) is an access point to the bladder and prostate.
- The ureters are anchored to the strong muscular backing of the trigone, which prevents reflux of urine.

Endoscopic Anatomy

The male bladder and urethra are easily visualized endoscopically in awake patients with local analgesia. Flexible fiberoptic cystoscopes enable complete visualization of the bladder, including the ureteral orifices and trigone, which can identify sources of hematuria and localize bladder tumors. At the bladder neck, retroflexion of the cytoscope can be performed to assess for intravesical protrusion of the prostate and to more readily identify small bladder tumors that lie just inside the bladder neck (Fig. 109.19A). The prostatic urethra can be visualized with the verumonatum located posteriorly and the ejaculatory ducts at the top (Fig. 109.19B). Withdrawing the cystoscope distally reveals the bulbar urethra, with coaptation of the extrinsic urethral sphincter evident just beyond the verumontanum (Fig. 109.19C). This anatomic landmark is important during transurethral resection of the prostate for benign prostatic enlargement, because deep resection in this area can damage the sphincter and result in incontinence.



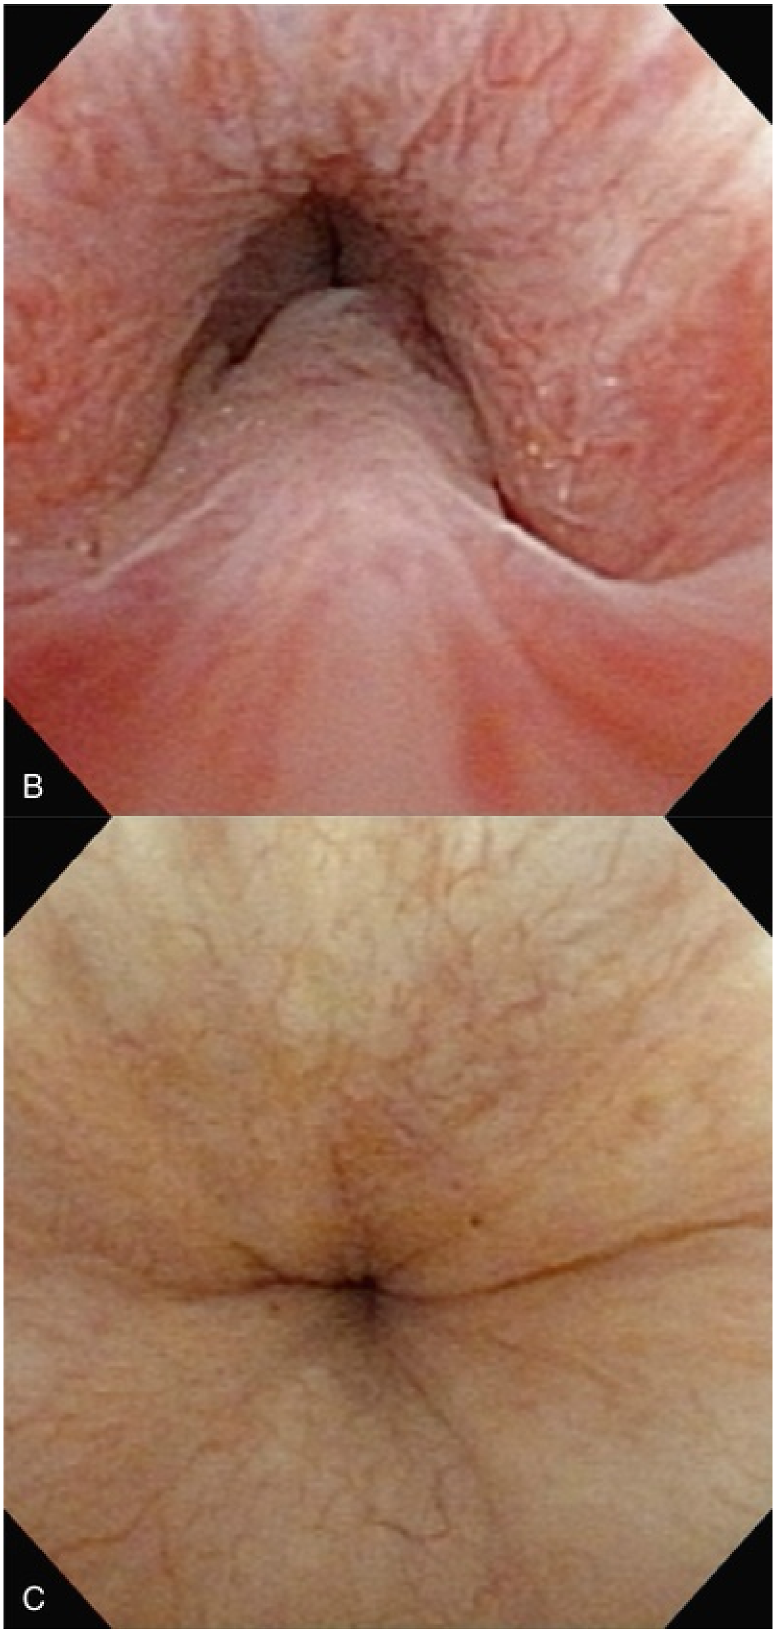


FIG. 109.19 Endoscopic view of (A) bladder neck with intravesical protrusion of prostate, (B) prostatic urethra with verumontanum, and (C) urethra showing good coaptation of the sphincter.

Radiographic Anatomy

Pelvic Radiographs and Fluoroscopy

Although pelvic radiographs and fluoroscopy show pelvic bony landmarks with high resolution and detail, the individual pelvic organs are generally poorly depicted by x-rays because of their similar densities. The bladder, for instance, can sometimes be seen when at least partially full as a faint line and rounded density in the middle of the pelvic ring, superior to the pubic symphysis. The rectum and sigmoid may be visualized and their size and location inferred by identification of gas bubbles or stool within the lumen outlining the wall. Calcifications are well seen in the pelvis, and the phlebolith (a calcification within a pelvic vein lumen) is essentially a normal finding, seen in up to 44% of pelvic x-rays (Mattsson, 1980). They have no clinical relevance but are important to recognize as they can mimic a distal ureter or bladder stone.

During fluoroscopic cystograms the empty bladder lies at or just above the pubic symphysis. As the bladder progressively fills with instilled contrast material, the bladder extends superiorly into the false pelvis (see Fig. 109.2B). Generally, the bladder stretches to occupy the lateral and anterior false pelvis extending toward the lateral pelvic sidewalls. Lack of bladder distention laterally may indicate space-occupying pelvic masses or fluid collections, classically resulting from extraperitoneal pelvic hematomas in the setting of pelvic trauma or lymphocele or hematoma after radical prostatectomy. Upon voiding the posterior urethra should be seen as a well-distended tube resulting from complete relaxation of the involuntary and voluntary urethral sphincter.

The posterior urethra is best imaged by retrograde urethrogram optimally performed in the oblique position. The posterior urethra comprises the membranous urethra, which passes through the urogenital diaphragm, and the prostatic urethra, extending from bladder base to the urogenital diaphragm. The membranous segment is the shortest segment and can be identified by its relationship just proximal to the cone of the bulbous urethra. The membranous segment is the narrowest part of the urethra and should not be mistaken for a stricture. It can be difficult to opacify the membranous and prostatic urethra with contrast because of voluntary external urethral sphincter contraction, but it is usually accomplished with steady injection pressure. The prostatic urethra is often tubular or somewhat flattened and is easy to identify because the verumontanum is seen as an oval central filling defect (see Fig. 109.2B). Once the prostatic urethra is opacified, contrast should flow freely into the bladder and show a triangular shape in the decompressed bladder or a vague, diluted pattern in a full bladder. Occasionally normal periurethral glands of Litre and Cowper ducts opacify alongside the posterior urethra, and these should not be mistaken for injuries or fistulae.

Computed Tomography

Modern computed tomography (CT) scans are acquired as a volumetric data set and can be reconstructed in any plane for viewing, although most commonly they are viewed in the axial, coronal, and sagittal planes. The inherent high spatial resolution of CT shows, in high anatomic detail, the pelvic organs and their relationships and allows for detection of various pathological conditions. Compared with magnetic resonance imaging (MRI), CT has a relatively low contrast resolution because most soft tissue organs and muscles are similar in density and consequently attenuate the x-ray beam similarly. Therefore most CT scans require injection of intravenous contrast to raise the attenuation of the organs to accentuate soft tissue contrast. The general exception to this rule is in imaging urolithiasis, in which intravenous contrast is unnecessary because the stones attenuate the x-ray beam strongly, resulting in high-contrast differences compared with the soft tissues. In the male, pelvis CT is primarily used for evaluating pain, infectious disease, stone disease, and postoperative complications and staging known malignancy. Detection of primary urologic malignancy is limited with most urologic tumors only seen at advanced local stage.

An important understanding of the peritoneal and extraperitoneal spaces is required to understand surgical anatomy, patterns of disease spread, and differential diagnosis of lesions. The abdominal wall peritoneum reflects over the dome of the bladder, and much of the bladder is surrounded by extraperitoneal spaces. The space of Retzius is seen at CT anterior to the bladder and communicates with lateral perivesicular spaces, both of which contain fat and vessels. Leaked urine accumulates in these spaces in the setting of extraperitoneal bladder rupture, and advanced bladder cancer may infiltrate these spaces. The peritoneum continues from the dome of the bladder into the retrovesical space as a pelvic peritoneal reflection of variable depth between the bladder and rectum. The retrovesical space is a common site of fluid accumulation or postoperative abscess formation because it is the most dependent portion of the peritoneum.

Lymph node evaluation is an important role of CT in patients with urologic malignancy. **Lymph nodes are well visualized by CT because of its spatial resolution. Normal lymph nodes appear as smooth, oval or elongated, homogenous soft-tissue density and may show fat density in the hilum where the vessels traverse.** Pelvic lymph nodes are found in specific locations adjacent to the major pelvic arterial divisions and are identified by named groups (Fig. 109.20). Size is the most commonly used criteria for abnormal lymph nodes with generally the highest specificity obtained at least 1 cm short axis. However, morphology is another criterion by which nodal metastasis can be assessed. Malignant nodes generally are rounded, heterogeneous, or hypervascular. Irregular and lobulated borders may be seen when there is extranodal extension of tumor.

FIG. 109.20 Axial contrast-enhanced CT through the mid-pelvis showing organ, vascular, lymph node, and muscle anatomy.

Contrast-enhanced CT can be performed as a multiphasic examination taking advantage of physiologic intravenous contrast dynamics. Because iodinated contrast is excreted almost exclusively through the kidneys, delayed imaging in the pelvis can be performed to show the ureters and bladder. These structures are filled with contrast typically at 7 to 10 minutes after injection, allowing for better visualization of the ureter course and wall, the bladder wall, and contents. Typically, this is accomplished with a CT urogram protocol, which allows for evaluation of the entire collecting system in one exam. The pelvic ureter is identified entering the pelvis as it crosses anteriorly and obliquely to the common or external iliac artery near the bifurcation (Fig. 109.21). A physiologic narrowing on CT urogram or pyelography can be seen at this point resulting from the vascular compression and turn as it passes over the pelvic brim. Further, it is not uncommon to identify undulations in the ureter diameter throughout its length resulting from normal peristaltic activity. Likewise, some segments of ureter may be unopacified with contrast because of peristalsis, and this should not be confused with disease. Continuing into the pelvis the ureter courses laterally along the pelvic sidewall and then takes an abrupt medial and anterior turn to enter the bladder at the ureterovesical junction (UVJ). On noncontrast axial images with thin-slice, modern CT, the ureter can almost always be followed along its entire course from the ureteropelvic junction (UPJ) to the bladder. Occasionally pelvic veins and other small structures can mimic the ureter, but if they are followed on subsequent slices, they will branch, disappear, or follow the incorrect anatomic course, unlike the ureter.

Magnetic Resonance Imaging

Although the resolution of CT and magnetic resonance imaging (MRI) can be similar, MRI shows more detailed muscle and soft-tissue anatomy in the male pelvis because of its higher soft-tissue contrast resolution, compared with CT. The pelvic organs, pelvic floor muscles, intervening fascia, vessels, and nerves are well depicted. Most MRIs are performed in multiple anatomic planes, using a combination of T1- and T2-weighted images with and without fat saturation pulses applied. **In general, T1-weighted images are best for evaluating osseous structures and muscles and to show post-contrast enhancement;** gadolinium contrast agents affect T1-weighted images much more than T2. T2-weighted images show detailed organ anatomy and muscles and are very sensitive to fluid, thereby showing edema, inflammation, and fluid collections well. In general, MRI images are best interpreted as a set, integrating the appearance of a lesion or organ across multiple T1 and T2 and post-contrast sequence types.

At pelvic MRI, the bladder is typically filled with urine, which is T2 hyperintense, whereas the wall is T2 dark. The bladder wall changes in thickness depending on the degree of distention. Generally, a normal, well-distended bladder has a wall thickness of less than 3 mm, whereas greater than 3 mm represents nonspecific pathologic thickening. The urethra can generally be followed throughout the course of the prostate gland, best identified on axial and sagittal images, usually traversing the midline posterior one-third of the gland (Fig. 109.22). In the mid-prostatic urethra the verumontanum is seen on axial images as a focal triangular or rounded bulge or filling defect within lumen (Fig. 109.23). This is the site where the ejaculatory ducts empty into the urethra, although generally the ducts are diminutive and cannot be seen by MRI in this location. The prostatic ducts, which empty throughout the urethra, are also not seen by MRI. The external urethral sphincter within the urogenital diaphragm lies just inferior to the apex of the prostate and is seen on axial images as a T2 dark donut-shaped structure of variable thickness (Fig. 109.24). Cowper glands within the urogenital diaphragm are normally not visualized unless enlarged or cystic.

FIG. 109.23 Axial T2-weighted MRI through the mid-prostate shows zonal prostate anatomy.

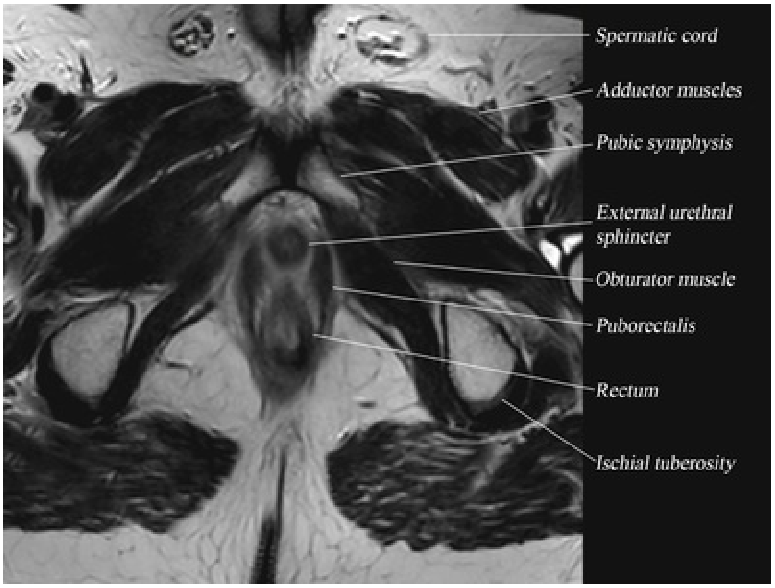

FIG. 109.24 Axial T2-weighted MRI through the pelvic floor shows the relationship of pelvic floor muscle and organ anatomy.

T2-weighted MRIs afford the best anatomic imaging assessment of the prostate gland, seminal vesicles, and supporting structures.

The pelvic organs are supported by the pelvic floor, a broad shelf or muscular plate comprising the levator ani complex, which is made up of three main muscles: puborectalis, pubococcygeus, and iliococcygeus. Puborectalis is a U-shaped muscle, best seen on axial images immediately superior to the external anal sphincter, passing from the inferoposterior aspect of the pubic bone, posteriorly, forming a sling around the anorectal junction (see Fig. 109.24). The muscle is important in the maintenance of voluntary urinary and fecal continence, and its function can be assessed at dynamic pelvic floor MRI. The pubococcygeus and iliococcygeus are thin, broad muscles extending from the pubic bone and lateral pelvic walls posteriorly to the coccyx, best seen on coronal images. Generally, they can be traced on MRI, but the individual fibers and insertions on pelvic organs are poorly depicted because of their small size. The pelvic organs are surrounded by endopelvic fascia, which also acts to support the organs. Endopelvic fascia generally appears as fat intensity on T1 or T2 images, and faint strands can be seen within representing connective tissue.

Below the pelvic floor, posteriorly, the internal and external anal sphincters are seen as separate structures at T2-weighted imaging, because the thick, donut-shaped smooth muscle fibers of the internal sphincter are more hyperintense compared with the thin, more vertically oriented external sphincter fibers (Fig. 109.25). Anteriorly below the urogenital diaphragm or triangle, the base of the penis is seen with the corpus cavernosa bodies appearing as T2-bright, almost fluid intensity structures because of their vascular contents. The midline corpus spongiosum appears similar, and generally the bulbous urethra wall can be seen as a faint T2-dark outline within. Thin, linear T2-dark fibers of the ischiocavernosus and bulbospongiosus muscles are seen adjacent to the corpus cavernosum and spongiosum, respectively (see Fig. 109.25).

Key Points: Radiographic Imaging of the Pelvis

- Radiographs provide high-resolution images of the bony pelvis.
- The urethra is best imaged by fluoroscopy.
- CT is better for urolithiasis, lymph nodes, and the urinary system.
- MRI has better soft-tissue resolution for the prostate and pelvic floor.

Physiology and Pharmacology of the Bladder and Urethra

Toby C. Chai MD, Lori A. Birder PhD

This chapter reviews physiologic mechanisms that regulate lower urinary tract (LUT) function. The LUT is composed of the bladder and urethra, and the two defining functions of the LUT are urinary storage and emptying. Although not the focus of this chapter, another LUT function is protection of the kidneys from ascending pathogenic microorganisms, which involves appropriate functioning of the urothelium and presence of a community of microorganisms (microbiome).

Urinary storage (continence) and urinary emptying (micturition) depend on the integrated function of many components, including the central nervous system (CNS), the peripheral nervous system, bladder smooth muscle, bladder stroma, suburothelial and intradetrusor interstitial cells, bladder urothelium, urethral smooth muscle, pelvic floor striated muscles, and the external urethral sphincter (EUS). An understanding of LUT physiology is essential for management of lower urinary tract dysfunction (LUTD), such as urinary incontinence, lower urinary tract symptoms (LUTS), overactive bladder (OAB), nocturia, neurogenic bladder, and underactive bladder. Improvements in physiologic understanding will improve diagnostic and phenotyping abilities and help discover the next generation of LUTD treatments.

Laboratory investigations into LUT physiology have used animal models, and most of the data discussed in this chapter are from animal studies. This is reasonable because interventions or experiments in human subjects are limited. **However, several reasons may mitigate the relevance of animal findings to humans.** The first consideration is use of lower-order mammals (i.e., mice and rats) as a model for human LUT function. Rodents are nocturnally active and their circadian rhythm is opposite of humans. Micturition is a behavior in which some animals mark their territory, a conduct that does not apply to humans. Whereas the clinical management of LUTS is almost entirely symptom based, LUTS are difficult (if not impossible) to quantify in animals, so surrogate parameters (such as micturition frequency and volume, urodynamics) that may not relate to symptoms have been used. Another consideration is whether research data were obtained from anesthetized or awake animals, because anesthesia can alter continence and micturition reflexes. However, animal models, no matter the potential drawbacks, will always be needed to improve our understanding of human LUTS. Novel findings can arise from findings in animal models (Gillespie, 2005). However, the importance of translational research, which seeks a bidirectional link between the bedside and bench, whether it is validating animal findings in humans or replicating a human phenotype in animals, is crucial in improving the treatment of LUTD.

The process of control of urinary storage and emptying is classically summarized as a complex of neural circuits in the brain and spinal cord that coordinate the activity of smooth and striated muscles in the bladder and urethra (de Groat and Booth, 1993; de Groat et al., 1993; Torrens and Morrison, 1987; Yoshimura and de Groat, 1997). These neural circuits act as switches that enable the bladder to alternate between urinary storage and elimination. Although this concept is important, translating physiologic understanding of LUT function into improved care for LUTD should be the ultimate goal. Furthermore, LUTD may not always arise from primary defects in nerves and/or muscles. Other biologic mechanisms can adversely affect LUT function, such as endocrine dysregulation (e.g., metabolic syndrome and obesity), inflammation (e.g., urothelial response to microorganisms), bladder or urethral fibrosis, and ischemia. Therefore LUTD can be a manifestation of mechanisms arising separately from the LUT.

The mechanisms underlying control of detrusor contractility and LUT sensation remain two major areas that would benefit from continued research because of the potential for clinical impact. Many conditions encountered in LUTD relate to these two parameters. A complexity of normal LUT function is that the bladder and urethra function necessarily in an opposite manner, thus making treatments that target only the bladder or only the urethra potentially ineffective and/or causing them to have unwanted side effects. For example, treatments directed at increasing bladder contractility for detrusor underactivity may not work if the treatments do not concomitantly relax the urethra. On the other hand, an example of how a more complete understanding of a single area can improve storage and emptying disorders is in the area of sensory (afferent) function. Modulation of sensory mechanisms could serve two purposes: reducing afferent signals could help those with LUTS, whereas augmenting afferent signals could help those with detrusor underactivity (Eastham and Gillespie, 2013; Suskind and Smith, 2009). Thus manipulation of the sensory pathway could preserve the requirement of coordinated yet simultaneously opposite bladder and urethral functions.

Although the management of LUTD is primarily symptom based at this time, use of biomarkers may come into play based on better physiologic understanding of the LUT. Ultimately, we should look forward to a time when targeted therapies and even prevention strategies may be incorporated into the management of LUTD patients.

Lower Urinary Tract Anatomy

The bladder can be divided into several parts: a **body** lying above the ureteral orifices and a **base** consisting of the trigone and bladder neck; the two areas are different but homogeneous within themselves regarding neuromorphology and neuropharmacology (el-Badawi and Schenk, 1966). The bladder base has a laminar architecture with a superficial longitudinal layer lying beneath the trigone (Fig. 110.1). A muscle layer deep to the superficial layer is continuous with the detrusor (Dixon and Gosling, 1987; Tanagho, 1982; Zderic and Levin, 1996). The smaller muscle bundles of the deep muscle layer in the bladder base exhibit a predominantly circular orientation. Histology of the full-thickness bladder is shown in Fig. 110.2A. A complete and competent ring of smooth muscle at the male bladder neck has been described (Gosling, 1999). No such collar of muscle is identified in the female. The bladder neck serves an important function in reproduction. **In men, closure of the bladder neck facilitates antegrade ejaculation. This is accompanied through a rich noradrenergic innervation by sympathetic nerves that actively contract the bladder neck during ejaculation. However, in women the density of adrenergic innervation in the bladder neck is reportedly less than that in men** (de Groat and Booth, 1993).

(B) The urothelium and lamina propria (200× magnification). (Courtesy Adebowale Adeniran, MD, Yale Department of Pathology.)

The urethra is part of the bladder outlet, along with the pelvic floor musculature. The urethra has components of smooth muscle and striated muscled (rhabdosphincter or EUS) (see Fig. 110.1). The periurethral striated muscle is part of the pelvic floor muscle complex.

Bladder Compartments

Urothelium

The urothelium is a multilayered epithelium with a basal, intermediate, and apical layer of cells. The apical cells (umbrella cells) make up the layer that is in contact with urine and microorganisms. The histology of the polarized urothelium is shown in Fig. 110.2B; the urothelium is about seven layers thick, with the largest cells being the apical (umbrella) cells, which are sometimes multinucleated. Although the anatomy of the urothelium is relatively straightforward, there are several physiologic functions, including barrier function (impermeability) and urothelial-afferent signaling, which are covered in later sections.

A scanning electron microscope (SEM) image of human apical urothelium, viewed from the luminal surface, is shown in Fig. 110.3. The SEM image was obtained from a biopsy forceps cystoscopic biopsy. Note the hexagonal shape of the apical urothelial cells and the microvilli on the surface. The apical cells are also unique in their expression of an assembly of a specialized class of proteins called *uroplakins*. The uroplakins are assembled within the apical membrane of the apical urothelial cells within specialized areas called *plaques*. The plaques have a membrane outer leaflet that is thicker than the inner leaflet, resulting in asymmetry. Thus the plaque region is also termed the *asymmetrical unit membrane* (AUM). The areas between the plaques are symmetrical in terms of the outer and inner leaflet thickness; this area is called the *hinge region*. Inside the AUM are chainmail-like ultrastructural hexagonal particles composed of uroplakins (Fig. 110.4). These ultrastructural particles are important in barrier function. The attachment of *Escherichia coli* type 1 fimbriae to uroplakins also initiates the host-pathogen interaction, initiating a cascade of host events (Mulvey et al., 1998; Thumbikat et al., 2009; Wu et al., 1996). More details of barrier function and urothelial-afferent crosstalk of the urothelium is described in later sections.

Lamina Propria and Vasculature

The lamina propria has been theorized to be the "functional center" for localized control of the bladder, coordinating the activities of the urothelium and detrusor smooth muscle (Andersson and McCloskey, 2014). Within the lamina propria, there is a diffuse plexus of unmyelinated nerve fibers making contact with urothelium, blood vessels, and detrusor smooth muscle. TRPV1 and $P2X_3$ receptors exist on nerve fibers that traverse the muscularis layer (Yiangou et al., 2001). In addition to the nerve fibers, other important structures in the lamina propria include interstitial cells (myofibroblasts) and microvasculature. The role of suburothelial myofibroblasts in detrusor contractility is discussed in a later section. These myofibroblasts positioned in the lamina propria are primed to modulate physiologic interactions between the urothelium and detrusor smooth muscle.

The anatomy of the microvasculature of the bladder in human and rabbit was studied using corrosion cast studies (Hossler and Monson, 1995; Miodonski and Litwin, 1999). The corrosion technique "fixes" the blood vessels by immediate vascular perfusion of the excised whole bladder with a fixative (e.g., a resin). Then all other tissue components of the bladder (smooth muscle, nerves, urothelium, stromal cells) were chemically digested, leaving only the vascular tree cast, which was imaged with scanning electron microscopy. The human bladder tissue studies showed a large horizontal plexus of blood vessels located in the lamina propria (termed the *mucosal plexus*) and another plexus just under the basal urothelial layer (termed the *subepithelial plexus*). Scanning electron microscopy of the mucosal vascular anatomy is shown in Fig. 110.5A, which shows a dense and rich submucosal plexus of vessels that lie immediately underneath the urothelium, the subepithelial capillary plexus. These are the vessels that would be typically seen during cystoscopy. Fig. 110.5B shows a schematic of what happens to the bladder vasculature during bladder filling and emptying. Blood flow through the subepithelial plexus may also be, in part, regulated by the urothelium. Furthermore, the subepithelial plexus could play a role for substances transported through or secreted by the urothelium.

This is viewed from the luminal side and shows the high density of the vessels that comprise the subepithelial capillary network (scale = 1000 µm). (B) Schematic of vasculature of empty bladder *(left)* and full bladder *(right).* Mucosal plexus (MP) and subepithelial capillary plexus (SCP) are in lamina propria. *AP,* Adventitial plexus. (From Miodoński AJ, Litwin JA: Microvascular architecture of the human urinary bladder wall: a corrosion casting study. *Anat Rec* 254:375–381, 1999.)

Because of the large increase in surface area of the bladder wall during filling, the blood vessels must be able to change length considerably. To maintain good blood flow, mechanisms may be needed to ensure that the overall resistance of the vessels, as they lengthen, does not increase sufficiently to reduce the effective perfusion of the tissue. Several groups have investigated the effects of bladder filling on the blood flow. The majority of reports have shown that the blood flow is reduced by distention (Batista et al., 1996; Greenland and Brading, 1996). In patients with low bladder compliance, there is a marked increase in the intravesicular pressure and a more pronounced decrease in bladder blood flow compared with normal controls (Ohnishi et al., 1994). **The principal determinant of blood flow in the bladder wall seems to be intramural tension. During normal filling, the blood flow is able to adapt to the large increase in surface area until the pressure in the bladder increases** (Greenland and Brading, 1996).

When the detrusor is deprived of oxygen or a metabolic substrate, as would occur in ischemia, its contractile ability rapidly declines (Levin et al., 1982, 2003; Pessina et al., 1997; Zhao et al., 1991). It has been suggested that ischemia and reperfusion may lead to damage to intramural neurons and result in the patchy denervation and altered smooth muscle function seen in bladders of patients with detrusor overactivity (DO) (Brading, 1997a). Investigators have also modeled pelvic ischemia (and thus bladder ischemia) in animals by inducing balloon injury to the internal iliac artery intima followed by high cholesterol diet to induce plaque formation. The ischemia led to changes in bladder function including detrusor overactivity and structural changes in the bladder (Azadzoi et al., 2010).

Stroma

The main constituents of bladder wall stroma are collagen and elastin in a matrix composed of proteoglycans. The main cells are fibroblasts. **The passive mechanical properties of the bladder wall depend on the viscoelastic properties of the stroma and of the relaxed detrusor muscle** (Cortivo et al., 1981). The stroma has commonly been considered a passive low-metabolic tissue that fills out the space among muscle bundles, vessels, and nerves. There has been increased appreciation for the role of the stroma in the adaptation of the bladder to pathophysiologic conditions (Macarak and Howard, 1999). Bladder hypertrophy is likely to involve an interaction of stroma and smooth muscle. In arteries, disruption of elastin in the stroma can stimulate proliferation of smooth muscle (Li et al., 1998). Although no such mechanisms are yet known in the bladder, it is possible that there could be a more intimate relationship between changes in the composition of the stroma and muscle function and growth than is appreciated at present.

Bladder Wall Collagen

Most of the bladder wall collagen is found in the connective tissue outside the muscle bundles. Changes in the relative amounts of muscle and nonmuscle tissue in the bladder wall would therefore influence collagen concentration. A number of different collagen types have been identified. In the bladder, **types I, III, and IV are the most common** (Andersson and Arner, 2004; Macarak et al., 1995). Investigators (Landau et al., 1994) developed morphometric and histochemical techniques to determine the percentage volume of connective tissue in the bladder wall and to measure the two major types (I and III) of collagen. These methods quantitate three parameters of bladder ultrastructure: percentage volume of connective tissue, ratio of connective tissue to smooth muscle, and ratio of type III to type I collagen. These parameters have been shown to be abnormally elevated in patients with bladder disease compared with normal patients. Landau et al. (1994) further studied the ultrastructural changes that occur in the wall of dysfunctional bladders to determine the ability of new urodynamic techniques to reliably detect the clinical effect of these histologic changes. The study included 29 consecutive patients undergoing bladder augmentation. Preoperative urodynamic evaluation included measurement of the total bladder capacity, assessment of pressure-specific bladder volume, and dynamic analysis of bladder compliance. Full-thickness bladder biopsy specimens were obtained from the dome of the bladders during augmentation. The percentage of connective tissue and the ratio of connective tissue to smooth muscle were determined for all patients. These histologic results were compared with previously established normal values. All 29 patients had decreased bladder compliance, even though 9 had a normal bladder capacity. **The ratio of connective tissue to smooth muscle was significantly increased in poorly compliant versus normal bladders. The ratio of type III to type I collagen was also significantly elevated. One can conclude that the poor storage function of poorly compliant bladders is secondary to an alteration in the connective tissue content of the bladder wall, especially increased collagen type III.**

In the rat, infravesical obstruction or bladder denervation induces hypertrophy of the detrusor smooth muscle and, in turn, a decrease in the collagen concentration (Uvelius and Mattiasson, 1984, 1986). Aging is associated with a relative decrease in smooth muscle in men and women, relative to collagen content (Lepor et al., 1992; Susset et al., 1978). This could perhaps be related to the decreased packing density of submucosal collagen during aging (Levy and Wight, 1990).

Perhaps the most comprehensive work on bladder collagen was performed by these investigators (Macarak and Howard, 1999), who speculated that connections must exist between the tension-generating elements (i.e., the smooth muscle cells) and the other components of the bladder. In bladders that become noncompliant (e.g., from spinal cord injury), it is likely that there is some interference with the ability of the collagen fibers to alter their tortuosity. This, predictably, would reduce total bladder capacity. Further studies are required to establish the relationship between compliance changes and the passive mechanical elements of the bladder wall that make up its structural protein matrix.

Bladder Wall Elastin and Matrix

Elastic fibers are amorphous structures composed of elastin and a microfibrillar component located mainly around the periphery of the amorphous component (Rosenbloom et al., 1995). In the mature fiber, the amorphous component makes up about 90%. The microfibrils contain a number of glycoproteins. Elastin fibers are sparse in the bladder compared with collagen but are found in all layers of the bladder wall (Murakumo et al., 1995). In spinal cord–injured rats, the elastin-to-collagen ratio increases over the first 6 weeks after injury. During this 6 weeks, the bladder compliance increases and the bladder becomes overdistended. Then the ratio is reduced as bladder compliance is decreased as a result of the emergence of DO 10 weeks after injury, suggesting a potential role for elastin in the modulation of bladder compliance (Nagatomi et al., 2005; Toosi et al., 2008).

The nonfibrillar matrix in the stroma is largely composed of a gel of proteoglycans and water. Proteoglycans are glycoproteins with glycosaminoglycans (GAGs) covalently attached. The arrangement of the proteoglycans in the matrix creates a compartment of tissue water that has a viscous behavior when it is subjected to deformation.

Smooth Muscle

Histologic examination of the bladder body reveals that myofibrils are arranged into fascicles (bundles) in random directions (Donker et al., 1982). The individual cells within a bundle are connected to form a functional syncytium. This architecture differs from the discrete circular and longitudinal smooth muscle layers in the ureter or gastrointestinal (GI) tract.

Bladder smooth muscles have no cross striations visible under the microscope. Each detrusor smooth muscle cell contains a single nucleus. The individual smooth muscle cells in the bladder wall are small spindle-shaped cells with a central nucleus; fully relaxed, they are several hundred micrometers long with a 5- to 6-µm maximum diameter (Smet et al., 1996). The cell membranes of smooth muscle contain caveolae—flask-shaped invaginations of the membrane—and elements of the intracellular sarcoplasmic reticulum (SR) are often associated with caveolae.

The motor innervation of the bladder smooth muscle is from the postganglionic parasympathetic nerve fibers, although intramural ganglia can exist within the bladder wall. Fig. 110.6 shows the varicosities (rounded nodes) that wrap around the smooth muscle fiber. Varicosities can release a variety of neurotransmitters including acetylcholine (ACh) and adenosine triphosphate (ATP). It is unlikely that every smooth muscle cell receives direct synaptic contact; the presence of gap junctions allows excitation to propagate throughout the smooth muscle syncytium. Postjunctional receptors, such as muscarinic and purinergic receptors, are present on the smooth muscle cell. When activated by their respective agonists, these receptors initiate the excitation-contraction events (see later section) of the smooth muscle. Some investigators have found that the detrusor smooth muscle has afferent innervation that could mediate afferent signals related to smooth muscle activity (Gillespie et al., 2006).

Overview of the Urethra

Male Urethra

The urethra begins at the bladder neck and extends to the external meatus and is composed of striated and smooth muscle. In the male, four segments are readily identified. The first is the preprostatic portion, or the bladder neck. The prostatic urethra then extends throughout the length of the gland, terminating at the prostatic apex. The membranous urethra extends from the prostatic apex through the pelvic floor musculature (including the EUS) until it becomes the bulbous and penile urethra at the base of the penis (Fig. 110.7). The male EUS covers the ventral surface of the prostate as a crescent shape proximal to the verumontanum, then assumes a horseshoe shape distal to the verumontanum, and is crescent shape at the bulbar urethra.

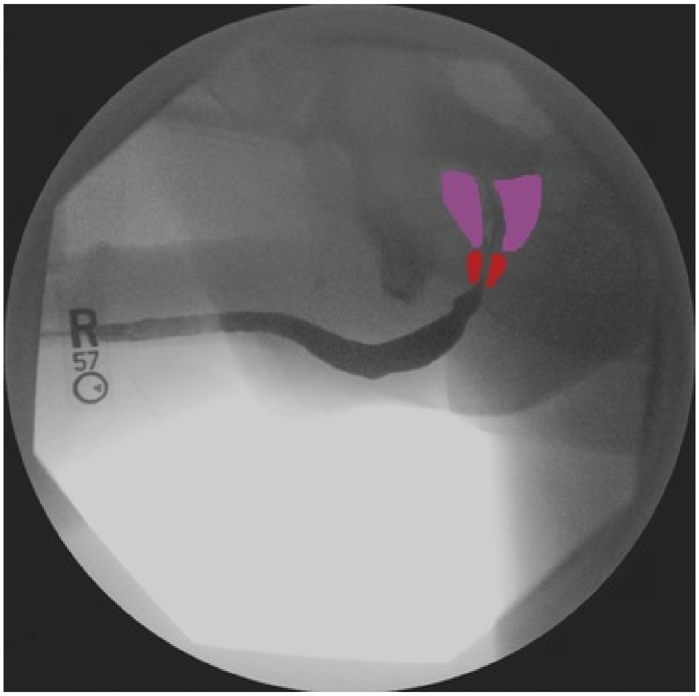

FIG. 110.7 Anatomy of male urethra seen on retrograde urethrogram with patient in lateral oblique position. The *red area* is the external urethral sphincter, and the *purple area* is the prostate.

Female Urethra

In women, the urethra extends throughout the distal third of the anterior vaginal wall from the bladder neck to the meatus. Detailed anatomic descriptions of structures along the female urethra are shown in Fig. 110.8. The urethra is composed of tissues that aid continence in addition to the urethral sphincter. **A network of vascular subepithelial tissue in women contributes to a urethral seal effect and promotes continence.** The EUS or rhabdosphincter (striated muscle) is under voluntary control and is part of the pelvic floor musculature. The female EUS covers the ventral surface of the urethra in a horseshoe configuration.

296, 2007.)

Urinary continence is maintained during elevations in intra-abdominal pressure by three processes. First, there is passive transmission of abdominal pressure to the proximal urethra. A guarding reflex involving an active contraction of striated muscle of the EUS can transiently help continence (Enhorning, 1961; Tanagho, 1982). However, mere transmission of abdominal pressure to the proximal urethra does not account for the entire increase in urethral pressure (Constantinou and Govan, 1982). Urethral pressure rises before cough transmission. These findings implicate an active urethral continence (neural) mechanism in women (Constantinou and Govan, 1982). DeLancey proposed the "hammock hypothesis"—that abdominal pressure transmitted through the proximal urethra presses the anterior wall against the posterior wall. The posterior wall remains rigid if there is adequate pelvic support from muscle and connective tissues. More distally, based on morphologic data, DeLancey and colleagues (DeLancey, 1989, 1997; Sampselle and DeLancey, 1998) postulated that the urethral attachments to the pubis (pubourethral) and vaginal connections to pelvic muscles and fascia actively change the position of the bladder neck and proximal urethra with voiding. This arrangement compresses the urethra against the pubis during bladder filling and straining. These attachments contain fascia and smooth muscle (Delancey, 1988; DeLancey, 1989; Oelrich, 1983). Thus urinary continence results from the combination of active muscle tone and passive anatomic coaptation.

Anatomy Common to Both Genders

Normal pelvic dissections of human urethral sphincters during different phases of gestational development were studied anatomically (Yucel and Baskin, 2004). The findings of this study were that development of the urethral sphincteric complex is similar in both genders. The urethral complex is derived from musculature from bladder detrusor, bladder trigone, and urethral muscles, each of different embryonic origin. These investigators found that the levator ani pelvic floor muscle does not surround the ventral aspect of the urethra in either gender, and the role of the levator ani in continence was questioned.

Fiber Types of Urethral Striated Muscle

Striated muscles are characterized as slow type and twitch type. Twitch-type myofibrils can be further classified as slow and fast on the basis of functional and metabolic characteristics (Padykula and Gauthier, 1967). Slow-twitch fibers seem ideally suited to maintaining sphincter tone for prolonged periods, whereas fast-twitch fibers may be needed to add to sphincter tone rapidly to maintain continence when intra-abdominal pressure is abruptly increased. Similar to smooth muscle, contraction of striated muscle fibers is governed by intracellular calcium, through interactions with troponin.

The fast-twitch fibers can be recruited rapidly but also fatigue rapidly and perform predominantly anaerobic metabolism (Markwardt and Isenberg, 1992). Fast-twitch fibers exhibit rapid bursts of contractile force and are rich in myosin ATPase that catalyzes the actin-myosin interaction. The speed of contraction may be correlated with the histochemical reaction of this ATPase and alkaline pH. In addition, fast-twitch muscles are supplied with a fast isoform of the Ca^{2+}-ATPase, which translocates the cytosolic calcium into the abundant SR to allow rapid relaxation.

In contrast, slow-twitch fibers are found in greater percentage in muscles that require sustained tension, such as the pelvic levators and urethral sphincter. These muscle fibers are recruited and fatigue slowly and can perform high rates of oxidative metabolism because they possess less of the myosin ATPase activity and contain an increased expression of a slow isoform of the Ca^{2+}-ATPase (Markwardt and Isenberg, 1992). These fibers give rise to the background electromyographic activity seen during a urodynamic evaluation.

The rhabdosphincter (EUS) is a skeletal muscle that is present in the walls of the urethra and is separate from the periurethral skeletal muscle of the pelvic floor. The muscle cells are smaller than ordinary skeletal muscle: 15 to 20 µm in diameter. **The EUS is composed of two parts. The periurethral striated muscle of the pelvic floor contains fast-twitch and slow-twitch fibers. The striated muscle of the distal sphincter mechanism contains predominantly slow-twitch fibers** (Elbadawi, 1984) **and provides more than 50% of the static resistance** (Tanagho et al., 1989). **Gosling et al.** (2000) **presented histochemical evidence in humans that striated muscle within the distal urethra is composed primarily of slow-twitch myofibrils in contrast to the periurethral striated muscles of the pelvic floor, which contain fast-twitch and slow-twitch fibers. In the male, the rhabdosphincter consists of 35% fast-twitch and 65% slow-twitch fibers** (Padykula and Gauthier, 1970). **In the female, the ratio of slow-twitch to fast-twitch fibers is 87% slow-twitch and 13% fast-twitch fibers.**

The majority of the fast-twitch fibers and about a fourth of the slow-twitch fibers in the intramural striated muscle of the human membranous urethral sphincter show positive staining for nitric oxide (NO) synthase (NOS) in the sarcolemma (Ho et al., 1998). Moreover, the striated periurethral muscles of the pelvic floor are adapted for the rapid recruitment of motor units required during increases in abdominal pressure. **It has been speculated that the successful treatment of stress incontinence by pelvic floor exercises or electrostimulation is caused by the conversion of fast-twitch to slow-twitch striated muscle fibers** (Bazeed et al., 1982).

In addition to striated muscle, the external sphincter appears to contain smooth muscle, which receives noradrenergic innervation. Investigators have shown that stimulation of the hypogastric nerve elicits myogenic potentials in the EUS (Kakizaki et al., 1991). Whether this activity is the result of smooth or striated muscle is unclear. Because these potentials persist after α-adrenergic blockade, investigators postulate that the activity arises from striated muscle.

Urothelial Physiology

Although the primary role of the urothelium is to form a relatively impermeable barrier to protect the underlying stroma of the bladder, other roles of the bladder urothelium include sentinel defense against uropathogenic bacterial infections, afferent signaling, and modulation of detrusor smooth muscle contractility.

Barrier Function

Epithelial permeability, including that of the urothelium, depends on a number of factors. These are passive diffusion, osmotically driven diffusion, active transport, and inertness of the membrane to the solutes to which it is exposed.

Descriptions of finite passage of substances across the urothelium are well known. In 1856 Kaupp reported that the composition and volume of urine were altered with 12-hour voiding patterns instead of hourly voiding. These changes in volume have also been noted in rats during isovolumetric cystometrograms during 3-hour periods (Sugaya et al., 1997), and the rate of water loss has also been estimated by direct measurement of passive water diffusion in vitro in the rabbit (Negrete et al., 1996). There is a passive permeability to most substances in the blood or urine (Hicks, 1975). In studies using an in vivo rat model, the bladder urothelium was permeable to urea, sodium, potassium, and chloride (Spector et al., 2011, 2013). The authors of these studies contend that the bladder modifies the final urinary concentration of these solutes and that this modification depends on the hydration status and dietary protein (Spector et al., 2012).

The human bladder urothelium is also permeable to water because of expression of the water transport protein aquaporin (Rubenwolf et al., 2009, 2012). Water permeability value in humans was measured at 6.5×10^{-5} cm/sec (Fellows and Marshall, 1972). This value was obtained by estimating the absorption of tritiated water into the plasma after instillation of the tritiated water into the bladder of volunteers. A direct measurement of urothelial diffusive permeability in the human has not yet been made. A measurement tool may help better phenotype LUTD that may be associated with increased urothelial permeability.

Breakdown of the apical (umbrella) cells in animal models of cystitis has shown increased water and urea permeability. Presumably, leakage of urinary solutes into the lamina propria is also responsible for the symptoms of cystitis (Lavelle et al., 1998, 2000). This increase in urothelial permeability with cystitis is increased further by distention of the bladder. The hypothesis is that with distention of the bladder, the weakened urothelium with denuded apical umbrella cells and no real barrier in the intermediate or basal cells is further disrupted, thus allowing further egress of urine constituents into the detrusor. Similar breakdown of the apical cells is thought to occur in most forms of infectious cystitis and also in radiation cystitis.

Direct measurements of the osmotic effect on permeability have not been performed on urothelium. However, the urothelium maintains an osmotic gradient between plasma (approximately 300 mOsm/kg) and urine (100 to 1500 mOsm/kg), depending on the level of water balance and diuresis of the individual. In the normal bladder, the osmotic effects of the urine appear to go unnoticed, and the patients have few or no symptoms. However, once the bladder is inflamed, as in bladder pain syndrome and interstitial cystitis (BPS/IC), the effects of osmotic gradients become important (Gao et al., 1994).

Patients with spinal cord injury or with myelodysplasia tend to have chronic cystitis with bacteriuria and inflamed urothelium. When detrusor activity was increased in the rat by instillation of hyperosmolar compounds, this was accompanied by neurogenic inflammation, including plasma extravasation of Evans blue that could be decreased by pretreatment with the C-fiber afferent neurotoxin capsaicin (Maggi et al., 1990), indicating that hyperosmolar solutions excite afferent nerves. With increased osmolality, detrusor contractions were much stronger and accompanied by blood pressure elevations. These effects were enhanced when the bladder was pretreated with dimethyl sulfoxide to simulate cystitis conditions (Hohlbrugger, 1987; Hohlbrugger and Lentsch, 1985).

Tight junction (TJ) proteins also contribute to the impermeability of the bladder urothelium. TJ proteins include zona occludens-1 (ZO-1), occludin, claudin-4, claudin-8, and claudin-12 (Acharya et al., 2004). TJs are present between cells to prevent paracellular (between the cell) permeability (Fig. 110.9). These TJ proteins adapt to stretch of the urothelium during filling and voiding without affecting permeability (of small molecules biotin, fluorescein, and ruthenium red), although there was a 10-fold drop in transepithelial resistance (TER) during urothelial stretch (Carattino et al., 2013). This drop in TER reflected increased ionic paracellular transport via claudin permeation pathway. In addition to these physiologic functions (barrier function, host response to pathogens) of the urothelium, the roles of urothelial-afferent signaling and modulation of smooth muscle contractility are covered in later sections.

The GAG layer, which has been described to be located on the luminal surface of the apical urothelial cell, has been a controversial subject of research into urothelial barrier function. *GAG* refers to a structure composed of 100% carbohydrate (polysaccharide). GAG is not produced through a template reaction as a protein is (DNA → RNA → protein), but rather through a series of enzymatic reactions within the cell. For this reason, GAG can be highly heterogeneous in molecular weight and composition. This GAG theory arose from findings of increased bacterial adherence to rabbit bladder urothelium after topical acid treatment and return to normal function with decreased adherence within 24 hours after acid injury, suggesting a “secretory” factor produced by the urothelium protecting the urothelium against bacterial adherence (Parsons et al., 1975). The secretory factor was reported to be GAG, based on the histology of rabbit bladders (Mulholland et al., 1976). However, using a different approach, it was found that the secretory factor was a glycoprotein (mucin glycoprotein MUC-1) rather than a polysaccharide (GAG) (Buckley et al., 1996; Higuchi et al., 2000). In an indirect method of examining the role of the GAG layer, Madin-Darby canine kidney (MDCK) cells were transfected with MUC-1. After this treatment, no difference in the transcellular water and urea permeability was found (Lavelle et al., 1997). Immunofluorescence study of human urothelium showed that chondroitin sulfate was the main GAG component, although the role of GAG in creating impermeability was studied in monolayer of cultured pig urothelial cells (Janssen et al., 2013). In summary, the GAG layer may have importance in bacterial antiadherence and in prevention of urothelial damage by large macromolecules. However, there is no definite evidence that the GAG layer acts as the primary impermeability barrier between urine and plasma in the human urothelium.

There seems to be no apparent difference between the urothelium of the trigone compared with the detrusor, in contrast to luminal cells lining the proximal urethra (Sun, 2006). In this urethral region, there is a transition from urothelium to a stratified or columnar epithelium accompanied by a lack of urothelial-specific differentiation markers. In addition, specialized chemosensory neuroendocrine cells are distributed within the urethral epithelia. These cells are often exposed to the lumen and may share similarities to GI enterochromaffin cells or chemosensory cells of the trachea or respiratory tract (termed “brush” cells or paraneurons) (Deckmann et al., 2014; Kullmann et al., 2018), including expression of microvilli. These urethral specialized chemosensory cells or “paraneurons” are able to respond to detect potential noxious stimuli (using the classic taste transduction pathway) by releasing mediators such as acetylcholine and even serotonin. Similar to urothelial cells in the bladder, these urethral chemosensory cells are also in proximity to sensory nerve fibers, whereby intraurethral stimulation can lead to activation of underlying cells, including bladder smooth muscle and sensory afferents. In this regard, evidence has shown that in vivo intraurethral administration of serotonin augments abdominal muscle wall activity termed a viscero-motor response (VMR) as well as afferent nerve activation. In addition, there are also reports that have identified functional properties of sacral afferents able to respond to changes in fluid flow through the urethra (Snellings et al., 2012). Although the functional significance of these findings and the number of distinct chemosensory cell types may not yet be fully appreciated, it is clear that such “sentinel” type cells are able to recognize potentially harmful stimuli (including bacteria) in the urethral lumen and in turn, alter bladder function.

Urethral Tone

There is controversy about the relative roles of the urethral smooth and striated circular muscles and the lamina propria in generating the urethral pressure profile, but it seems likely that both contribute (Thind, 1995). **Blocking striated sphincter activity with nicotinic neuromuscular blocking agents has variable effects and may reduce urethral tone but rarely by more than 40%, suggesting that the smooth muscles are important. Blocking sympathetic tone with α-adrenoceptor blockers may also reduce urethral pressure by about a third** (Torrens and Morrison, 1987). There is little evidence for the involvement of the cholinergic innervation in generating urethral pressure.

Despite the horseshoe configuration with the open end in the posterior direction, urethral pressure recording at the external sphincter during bladder filling increases uniformly along the entire circumference like an iris (Morita and Tsuchida, 1984). Norepinephrine or hypogastric nerve stimulation augments this pressure, suggesting a role for adrenergic receptors and sympathetic nerves in the function of the EUS (Kakizaki et al., 1991).

The urethral stroma contains primarily longitudinally arranged collagen fibers and elastin fibers (Hickey et al., 1982; Huisman, 1983). The vascular filling of the urethral lamina propria is known to be of importance for urinary continence, although the magnitude of its contribution to continence is still not understood (Rud et al., 1980). Estrogen is known to increase the urethral blood flow, resulting in increased distention of the lamina propria blood vessels (Brading, 1997a).

Impaired arterial blood supply to the urethra decreases the intraluminal pressure (Rud et al., 1980), but at present it is not known whether it is the decrease in vascular filling or the urethral hypoxia that mediates the decrease in urethral pressure. It has been suggested that both these mechanisms may be involved because it was shown that the initial drop in urethral pressure was mediated through decreased vascular filling, whereas the later phase was the result of a hypoxic effect on the urethral smooth muscle (Greenland and Brading, 1996).

Results are divergent regarding the clinical significance of connective tissue outside the urethra. Paraurethral tissue biopsy specimens from premenopausal women with stress incontinence contain 30% more collagen, and the diameter of the fibrils is 30% larger than in controls (Falconer et al., 1998a). Postmenopausal stress-incontinent women, on the other hand, have no difference in collagen concentration compared with their age-matched controls (Falconer et al., 1998b). Others, however, have found a decreased periurethral collagen concentration (Rechberger et al., 1993) and a decreased ratio of collagen I to collagen III (Keane et al., 1997) in patients with stress incontinence.

Ionic Transport

The apical membrane of the urothelium has a high electrical resistance (Lavelle et al., 1998, 2000), whereas the basolateral membrane resistance is approximately 10-fold lower (Clausen et al., 1979). Active sodium transport across the urothelium has been demonstrated (Lewis and Diamond, 1976; Wickham, 1964). Na^+ channels that exist on the apical surface of the umbrella cells and in the cytoplasmic vesicles below the apical surface are primarily amiloride sensitive (inhibition) and aldosterone responsive. However, amiloride-insensitive, cation-selective, as well as amiloride-insensitive, unstable cation channels have also been identified. Both of these channels were found to be degradation products of the amiloride-sensitive Na^+ channel. The amiloride-sensitive Na^+ channel is hydrolyzed by serine proteases such as kallikrein and urokinase and plasmin (normally found in the urine but produced by the kidney) (Lewis et al., 1995). Studies of rat bladders have shown that urea, sodium, potassium, and chloride can cross the bladder urothelium and be taken up by suburothelial blood vessels (Spector et al., 2011, 2012, 2013).

Sodium that is transported into the cell is removed at the basolateral membrane by an Na^+-K^+ exchanger. This leaves the cell with a negative intracellular charge. The basolateral membrane contains K^+ and Cl^- channels, Na^+-H^+ exchangers, and Cl^--HCO_3^- exchangers. These channels and exchangers are important in recovery of cell volume during an increase in serosal osmolality (Donaldson and Lewis, 1990). Unfortunately, the precise role of the Na^+ channel in the apical membrane of the umbrella cell is unknown. It is possible that the degradation of the channel may follow the filling of the bladder and that the changes in conductance of sodium may be a signaling factor for the bladder and micturition when it reaches capacity. Alternatively, it may be involved in the signaling pathway that allows insertion or removal of apical membrane on expansion of the bladder.

Sensor-Transducer Function of the Urothelium

Whereas the urothelium has historically been viewed primarily as a barrier, there is increasing evidence that urothelial cells display a number of properties similar to sensory neurons (nociceptors and mechanoreceptors) and that both types of cells use diverse signal-transduction mechanisms to detect physiologic stimuli. Examples of “sensor molecules” (i.e., receptors and ion channels) associated with neurons that have been identified in urothelium include receptors for bradykinin (Chopra et al., 2005), neurotrophins (TrkA and p75) (Murray et al., 2004), purines (P2X and P2Y) (Birder et al., 2004; Chopra et al., 2008; Hu et al., 2002; Lee et al., 2000; Sun and Chai, 2004; Tempest et al., 2004), norepinephrine (α and β) (Birder and de Groat, 1998; Birder et al., 1998, 2002), ACh (nicotinic and muscarinic) (Beckel et al., 2006; Chess-Williams, 2002; Kullmann et al., 2008b) protease-activated receptors, amiloride-mechanosensitive Na$^+$ channels such as ENaC (Araki et al., 2004; Smith et al., 1998; Wang et al., 2003), and a number of transient receptor potential (TRP) channels (TRPV1, TRPV2, TRPV4, TRPM8) (Birder and de Groat, 1998; Birder et al., 2001, 2002, 2007a, 2007b; Gevaert et al., 2007; Stein et al., 2004).

When urothelial cells are activated through these receptors and ion channels in response to mechanical as well as chemical stimuli, they can, in turn, release chemical mediators such as NO, ATP, ACh, and substance P (SP) (Birder and de Groat, 1998; Birder et al., 1998, 2003; Burnstock, 2001a, 2001b; Chess-Williams, 2004; Ferguson et al., 1997). These agents are known to have excitatory and inhibitory actions on afferent nerves that are close to or in the urothelium (Bean et al., 1990; Birder et al., 2001; Yoshimura et al., 2008). Video 110.1 ▶ shows urothelial cells responding to increasing doses of extracellular carbachol, a nonselective muscarinic agonist, with increasing concentrations of intracellular Ca^{2+} (fura-2 ratio).

Chemicals released from urothelial cells may act directly on afferent nerves or indirectly through an action on suburothelial interstitial cells (also referred to as *myofibroblasts*) that lie in close proximity to afferent nerves. Myofibroblasts are extensively linked by gap junctions and can respond to chemicals that in turn modulate afferent nerves (Fowler et al., 2008). Thus it is believed that urothelial cells and myofibroblasts can participate in sensory mechanisms in the urinary tract by chemical coupling to the adjacent sensory nerves.

NO can be released by the urothelium, particularly during inflammation (Birder and de Groat, 1998; Birder et al., 1998). The release of NO may be evoked by the calcium ionophore A-23187, norepinephrine, and capsaicin. SP also acts on receptors on urothelial cells to release NO. The adrenergic release of NO from bladder strips was reduced by 85% after removal of the urothelium. Denervation of the bladder did not completely block the release of capsaicin-induced NO production, suggesting other sites of production. This is consistent with the observations that capsaicin released NO from cultured rat, cat, rabbit, and human urothelial cells and that the TRPV1 capsaicin receptor is expressed in cultured urothelial cells. NOS expression in afferent neurons is also increased in chronic bladder inflammation. Given that NO does not have much effect on the detrusor muscle but does inhibit Ca^{2+} channels in rat bladder afferent neurons (Yoshimura et al., 2001), **the role of NO in the urothelium has still to be clarified.** However, **NO released locally in the bladder appears to have an inhibitory effect on afferent activity in the bladder** because suppression of endogenous NO by intravesical oxyhemoglobin, an NO scavenger, or L-NAME, a NOS inhibitor, enhances bladder activity in rats (Masuda et al., 2007; Pandita et al., 2000).

ATP released from urothelial cells during stretch can activate a population of suburothelial bladder afferents expressing $P2X_3$ receptors, signaling changes in bladder fullness and pain (Burnstock, 2001a; Ferguson et al., 1997). Accordingly, $P2X_3$ null mice exhibit a urinary bladder hyporeflexia, suggesting that this receptor, as well as neural-epithelial interactions, are essential for normal bladder function (Cockayne et al., 2000). This type of regulation may be similar to epithelium-dependent secretion of mediators in airway epithelial cells, which are thought to modulate submucosal nerves and bronchial smooth muscle tone and may play an important role in inflammation (Homolya et al., 2000; Jallat-Daloz et al., 2001). Thus it is possible that activation of bladder nerves and urothelial cells can modulate bladder function directly or indirectly by the release of chemical factors in the urothelial layer. ATP released from the urothelium or surrounding tissues may also play a role in the regulation of membrane trafficking. This is supported by studies in the urinary bladder in which urothelium-derived ATP release purportedly acts as a trigger for exocytosis, in part by autocrine activation of urothelial purinergic (P2X, P2Y) receptors (Wang et al., 2005). These findings suggest a mechanism whereby urothelial cells sense or respond to ATP and thereby translate extracellular stimuli into functional processes.

A study showed that human bladder urothelial tissue behaved similarly to guinea pig bladder urothelium. Both urothelia released ATP in response to muscarinic and purinergic stimulation (Sui et al., 2014). The released ATP induced contraction of the urothelial mucosal tissue. Aging was associated with increased ATP release. These findings continue to support the hypothesis that the urothelium is capable of sensing and transducing signals and likely modulates overall bladder function.

Prostaglandins are also released from the urothelium. These are assigned two possible functions: regulation of detrusor muscle activity and cytoprotection of the urothelium, based on effective treatment of hemorrhagic cystitis by prostaglandins (Jeremy et al., 1987). The predominant forms found in human urothelium from biopsy specimens are 6-oxo–prostaglandin $F_{2\alpha}$ ($PGF_{2\alpha}$) more than PFE_2 more than $PGF_{2\alpha}$ more than thromboxane B_2. PGI_2 (prostacyclin) is also produced. These findings were confirmed and further developed in the guinea pig, in which it was found that the major production of prostaglandins occurred in the urothelium. The production of prostaglandins also increased greatly with inflammation (Saban et al., 1994). Prostaglandin synthesis also occurs in the ureter, where it is speculated to be important in the regulation of ureteral peristalsis and also in reducing the development of blood clots in the lumen of the ureter (Ali et al., 1998).

Evidence also suggests that the involvement of the muscarinic receptor in bladder function extends beyond detrusor contractility and into afferent sensory functioning. Muscarinic receptors are found on the urothelium at high density (Hawthorn et al., 2000), and there is a basal release of ACh from the urothelium that is increased by stretch and aging (Yoshida et al., 2006). Thus activation of the muscarinic receptors in the urothelium releases substances that modulate afferent nerves and smooth muscle activity (de Groat, 2004; Hawthorn et al., 2000; Kullmann et al., 2008a).

The urothelium also releases substances called *urothelium-derived inhibitory factors,* which decrease the force of detrusor muscle contraction in response to muscarinic stimulation (Hawthorn et al., 2000; Kumar et al., 2005). The molecular identity of this factor is not known; however, pharmacologic studies suggest that it is not NO, a prostaglandin, prostacyclin, adenosine, catecholamine, γ-aminobutyric acid (GABA), or a factor that acts through apamine-sensitive, small-conductance K^+ channels. It has been shown that an inhibitory response through this factor is attenuated in a fetal model of bladder outlet obstruction (BOO) (Thiruchelvam et al., 2003). Further studies are required to clarify the identity of this substance and its role in bladder function.

Suburothelial Interstitial Cells

In the human bladder, subepithelial interstitial cells, which are also called **myofibroblasts,** are located just below the basal layer of the urothelium. These myofibroblasts stain for vimentin and α-smooth muscle actin but not for desmin (Fry et al., 2004). These cells are linked by gap junctions consisting of connexin 43 (Cx43) proteins and make close appositions with C-fiber nerve endings in the submucosal layer of the bladder, suggesting that **there is a network of functionally connected interstitial cells immediately below the urothelium that may be modulated by other nerve fibers** (Fry et al., 2004; Fig. 110.10). ATP can induce inward currents associated with elevated intracellular Ca^{2+} in isolated suburothelial interstitial cells (Fry et al., 2007).

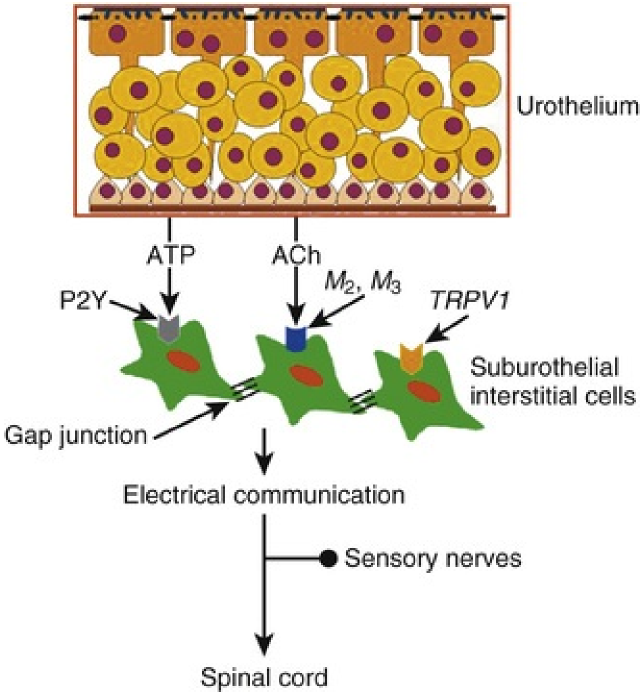

FIG. 110.10 Schematic representation of suburothelial interstitial cells, which are also called *myofibroblasts.* Substances released from the basolateral surface during stretch, such as adenosine triphosphate (ATP) and acetylcholine (ACh), activate afferents in the suburothelial layer through the intermediation of suburothelially located interstitial cells, which express purinergic P2Y receptors, muscarinic M_2 and M_3 receptors, or capsaicin TRPV1 receptors, and are connected to one another by gap-junction proteins.

Immunohistochemical studies show the expression of P2Y receptors, most notably $P2Y_6$ receptors, and M_3 muscarinic receptors in suburothelial interstitial cells from guinea pigs (Fry et al., 2007; Grol et al., 2009). In the human bladder, increased expression of muscarinic M_2 and M_3 receptors in vimentin-stained suburothelial interstitial cells is found and correlates with the urgency score in humans with idiopathic detrusor overactivity (IDO) (Mukerji et al., 2006). Because ATP or ACh is known to be released from the urothelium during bladder stretch, **suburothelial interstitial cells are in an ideal position between the urothelium and nerve endings to modify a sensory feedback mechanism.** Application of an NO donor sodium nitroprusside (SNP) also attenuates an increase in intracellular Ca^{2+} and current responses to ATP in guinea pig interstitial cells, suggesting the cyclic guanosine monophosphate (cGMP)–dependent inhibition of cell activity (Sui et al., 2008).

Key Points: Urothelium

- Uroplakin proteins and TJ proteins play key parts in urothelial barrier function.
- Uroplakins have also been shown to act as the primary attachment site of type 1 piliated uropathogenic *E. coli*.
- The GAG layer may have importance in bacterial antiadherence, but there is no definite evidence that the GAG layer serves impermeability function.
- Urothelial cells can release and respond to neurotransmitters.
- Myofibroblasts mediate interaction between urothelial cells and afferent nerves.

Smooth Muscle Physiology

Studies on bladder smooth muscle physiology have been a mainstay for understanding micturition function, because the detrusor smooth muscle must contract for the bladder to empty efficiently and normally. Understanding the factors that regulate smooth muscle quiescence could be applicable to clinical conditions characterized by DO such as OAB, neurogenic bladder, and underactive detrusor. Function of the smooth muscle, like striated muscle, is regulated by motor nerves (although autonomic rather than somatic), but unlike striated muscle, smooth muscle function can also be modulated by circulating hormones, local paracrine factors such as NO, and factors released by the urothelium. Although the coordinated and efficient contractions of the detrusor smooth muscle require neural control, detrusor muscle can generate spontaneous and rhythmic activity without neural input. The differences between smooth muscle versus striated muscle properties are shown in Table 110.1 (Chacko et al., 1999). The next several sections address physiologic aspects of detrusor smooth muscle function starting at the individual smooth muscle cell and moving to the whole organ level.

TABLE 110.1

Comparison of the Properties of Skeletal and Smooth Muscle

PROPERTY	SKELETAL MUSCLE	SMOOTH MUSCLE
Cell characteristics	Long cylindric cells with many nuclei	Spindle-shaped cells with a single nucleus
Maximum cell size (length × diameter)	30 cm × 100 µm	200 µm × 5 µm
Visible striations	Yes	No
Ultrastructure	Sarcomere pattern	No sarcomere pattern
	No immediate filaments	Intermediate filaments
		Dense bodies
Motor innervation	Somatic	Autonomic
Type of contracture	Phasic	Mostly tonic, some phasic
Contractile activity	Disinhibition of tropomyosin	Active myosin phosphorylation
	Sliding filaments	? Sliding filaments
	Rapid contraction	Formation of “latch state”

Calcium regulation	Rapid Ca^{2+} influx via T tubule	Voltage- and receptor-operated Ca^{2+} channels
		Release from internal stores
Basic muscle tone	Neural activity	Intrinsic, extrinsic factors
Force of contraction regulated by hormone	No	Yes

Contractile Proteins

Bladder (detrusor) smooth muscle cells contract by the interaction of thick and thin filaments within the intracellular cytoskeletal network. Thick filaments (15-nm diameter) are composed of myosin. Thin filaments (6- to 8-nm diameter) are composed mainly of actin. Bound to actin are tropomyosin (TM) and caldesmon (CaD), both of which are important in regulation of contraction. Intermediate filaments (10 nm in diameter) are composed of desmin and vimentin. Whereas contraction of smooth muscle cells is caused by the cross-bridge cycling between the thick and thin filaments, intermediate filaments can modulate the contractile response (see review by Tang [2008]). The thin and thick filaments of smooth muscle fibers are arranged as myofibrils that cross the fibers obliquely in a lattice-like arrangement, rather than the organized linear fashion of the sarcomere in striated muscle fibers. The thin and intermediate filaments attach to multiple sites within the cytoplasm (sarcoplasm) at locations called *dense bodies* (Fig. 110.11). The filaments of contractile proteins are also attached to the plasma membrane at junctional complexes between neighboring cells, which allow smooth muscle cells to contract as a syncytium.

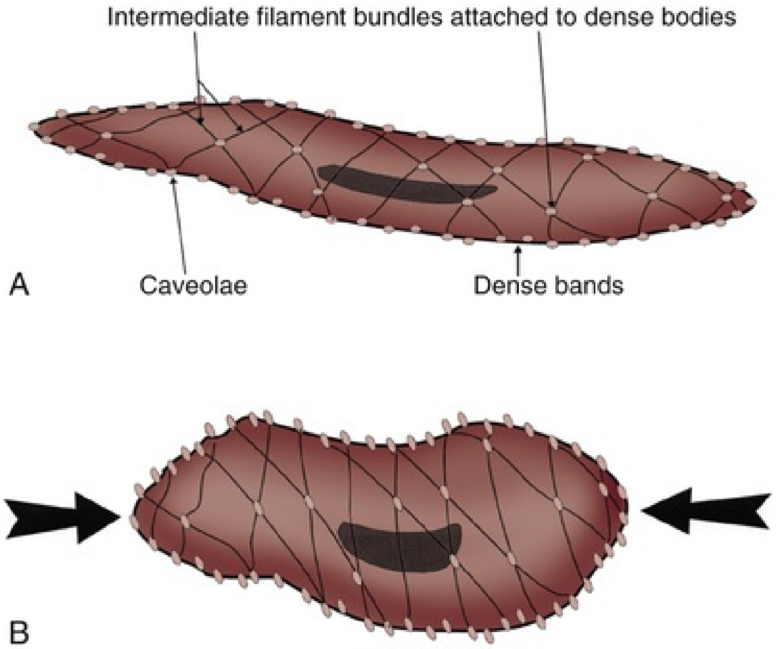

FIG. 110.11 The organization of the contractile elements of smooth muscle fibers by a simple model of the contraction of smooth muscle. (A) Relaxed smooth muscle cell. (B) Contracted smooth muscle cell. Intermediate filaments, dense bodies, and dense bands of smooth muscle fibers harness the pull generated during myosin cross-bridge activity. Intermediate and thin filaments attach to dense bodies scattered throughout the sarcoplasm and occasionally anchor to the dense bands situated between caveolae (invaginations of the sarcolemma). As the obliquely running contractile elements contract, the muscle shortens.

Thick filaments are made up of myosin II—two intertwined myosin heavy chains (MHCs) (Fig. 110.12) (as opposed to myosin I, which contains only one MHC). There are two areas of myosin II: the rod portion, which contains the coil region, and the head region, which contains globular domains of the two MHCs with an intervening hinge region between the coil and head. Alternative splicing of MHCs pre-mRNA at the 5′-end produces SM-A and SM-B isoforms of MHC, whereas alternative splicing at the 3′-end produces SM-1 and SM-2 isoforms of MHC. The bladder smooth muscle contains almost 100% SM-B. SM-B has a higher ATPase activity than SM-A; therefore SM-B can move actin filaments faster in an in vitro assay (Rovner et al., 1997).

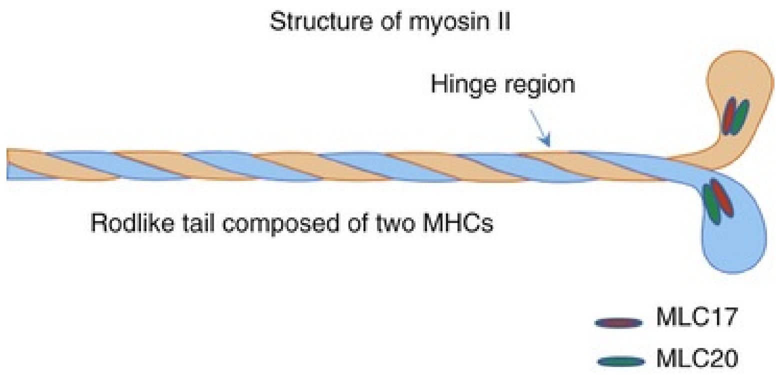

FIG. 110.12 Structure of myosin II composed of two intertwined myosin heavy chains (MHCs). MLC17 and MLC20 are two myosin light chains located on heads of myosin II.

Contained within each globular region of the MHC are two myosin light chains (MLCs), MLC20 (20 kDa) and MLC17 (17 kDa). These two MLC isoforms are encoded by different genes, but only one relates to contractility. Two MLC17 variants occur as a result of alternative splicing of a single MLC17 gene. **Cross-bridge cycling depends on the phosphorylation of MLC20, which increases the activity of an enzyme, myosin ATPase.**

Although studies of interactions between actin and myosin in cross-bridge cycling have been canonical in understanding smooth muscle contractility, the unique role of actin has been recognized and reviewed (Gunst and Zhang, 2008). The structure and organization of filamentous actin was thought to remain relatively constant during a contractile event. Furthermore, it was assumed that actin filaments anchored at adhesion sites at the plasma membrane and at dense bodies within the cytosol (see Fig. 110.11), which provides a fixed and stable network on which the myosin or thick filaments move during shortening and tension development. However, intracellular actin polymerization is now recognized as a seminal event in smooth muscle contraction. This actin polymerization also catalyzes recruitment of structural proteins that connect actin filaments and transmembrane integrin proteins to adhesion junctions (Fig. 110.13).

Activated smooth muscle cell

FIG. 110.13 Figure shows a single myocyte going from relaxation to contraction. The importance of actin polymerization at the periphery of the cell is that this network strengthens the membrane for force transmission from the actinomyosin cross-bridges. The regulation of actin polymerization is distinct and separate from actinomyosin cross-bridge cycling. (From Gunst SJ, Zhang W: Actin cytoskeletal dynamics in smooth muscle: a new paradigm for the regulation of smooth muscle contraction. *Am J Physiol Cell Physiol* 295:C576–C587, 2008.)

The interaction between actin and myosin in smooth muscle contractions is modulated by the actin-binding (actin-associated) proteins caldesmon (CaD) and tropomyosin (TM) (Fig. 110.14). These two proteins control access points on the actin filament to allow myosin II heads to form cross-bridges. Fig. 110.14 shows that CaD interacts with all of the contractile proteins and also calmodulin (CaM). CaD was first isolated from chicken gizzard smooth muscle in 1981 (Sobue et al., 1981). There are two isoforms of CaD: heavy CaD (h-CaD), which is associated with all smooth muscle, and light CaD (l-CaD), which is found in non–smooth muscle cells. CaD is an inhibitor of actinomyosin ATPase and motility, and actin binding and CaD inhibition are greatly enhanced in the presence of TM. Detailed descriptions of CaD functions have been reviewed (Wang, 2008). CaD is modulated by another protein, CaM. Although CaM is technically not a contractile protein, CaM is the protein that interacts with intracellular Ca^{2+} to initiate the contraction.

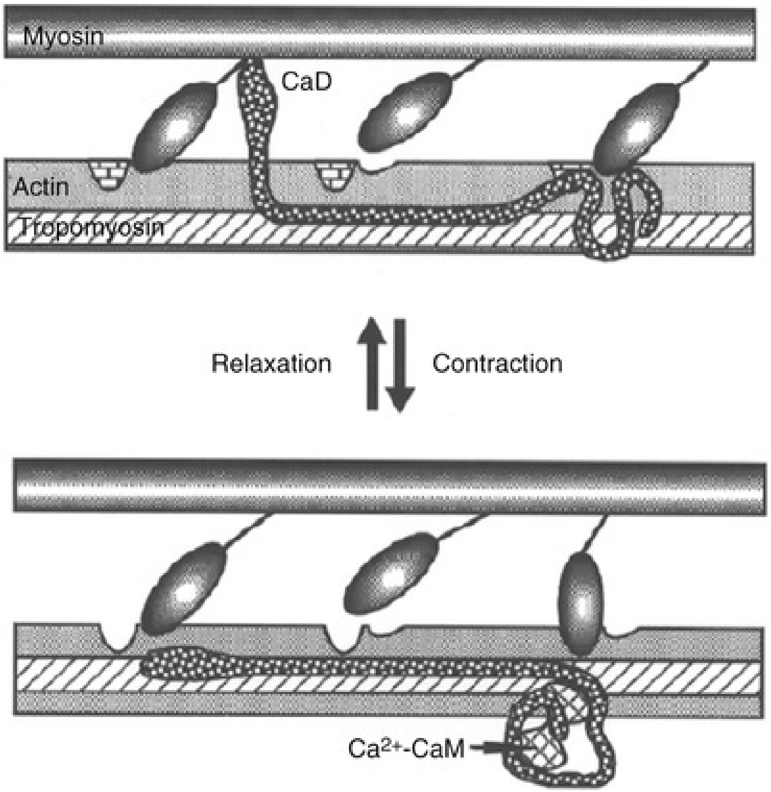

FIG. 110.14 Caldesmon (CaD) and tropomyosin are actin-bound proteins that regulate actinomyosin cross-bridging. CaD and tropomyosin move along the actin filament to expose actin binding sites for the head region of myosin II to generate contraction. (From Shirinsky VP, Vorotnikov AV, Gusev NB: Caldesmon phosphorylation and smooth muscle contraction. In Kohama K, Sasaki Y, editors: *Molecular mechanisms of smooth muscle contraction,* Austin, TX, 1999, RG Landes Company.)

Actinomyosin Cross-Bridge Cycling

The key step in smooth muscle cellular contraction is cross-bridge formation of myosin II heads to actin, which is dependent on rise of intracellular Ca^{2+}. When an action potential (AP) occurs in the smooth muscle cell, there is a rise in intracellular Ca^{2+}, which then binds to CaM, thereby activating myosin light chain kinase (MLCK) (Andersson and Arner, 2004; Gunst et al., 1993; Hai and Murphy, 1989). MLCK phosphorylates MLC20, which is in the head region of myosin II, cleaving a phosphate moiety in ATP, thus converting ATP to adenosine diphosphate (ADP) in the process. Phosphorylated MLC20 forms cross-bridges with (i.e., binds to) actin, leading to force generation (Andersson and Arner, 2004; Chacko et al., 1994; Gunst et al., 1993; Hai and Murphy, 1989; White et al., 1993). Dephosphorylation of MLC20 is catalyzed by myosin light chain phosphatase (MLCP), leading to detachment of the myosin II heads from actin and relaxation. An animation of these interactions is shown on the Expert Consult website. Key points in the smooth muscle contraction sequence are also presented in Box 110.1.

Box 110.1

Detrusor Smooth Muscle Contraction Sequence

- Ca^{2+} binds to calmodulin (CaM), activating it.
- CaM activates the kinase enzyme (myosin light chain kinase).
- The kinase enzyme catalyzes phosphate transfer from adenosine triphosphate to myosin, allowing myosin to interact with actin of the thin filaments.
- Smooth muscle relaxes with intracellular decrease in Ca^{2+} levels.

The determination of smooth muscle tone is therefore dependent on the balance of intracellular Ca^{2+} and the balance between MLCK and MLCP activities. Although Ca^{2+} is needed for MLCK activity, regulation of MLCP activity plays an important role in smooth muscle contractility. **Inhibition of MLCP activity promotes contractility and tone in the smooth muscle cell in the absence of increases in intracellular Ca^{2+} changes *(calcium sensitization)*. It has been shown that MLCP activity is under control of a series of complex molecular events related to two proteins, RhoA and Rho kinase (ROK).**

RhoA is part of a family of proteins known as *small GTPases*. The activity of RhoA (active vs. inactive forms) is based on the form of guanine phosphate bound to RhoA. Inactive RhoA is bound to guanosine diphosphate (GDP) (Rho-GDP), and active RhoA is bound to guanosine triphosphate (GTP) (Rho-GTP). Three classes of regulatory proteins control the cycling between active RhoA and inactive RhoA forms: (1) guanine nucleotide exchange factors (GEFs), which convert RhoA-GDP to Rho-GTP; (2) GTPase-activating proteins (GAPs), which convert Rho-GTP to Rho-GDP; and (3) guanine nucleotide dissociation inhibitors (GDIs), which bind to RhoA-GDP and prevent action of GEFs and prevent RhoA-GDP from translocating from cytosol to cellular membrane, which inhibits the activity of RhoA (Puetz et al., 2009).

Activated RhoA, RhoA-GTP, binds to ROK at the cellular membrane to activate ROK. **Activated ROK phosphorylates MLCP, inactivating MLCP, thus tipping the balance toward contraction of the smooth muscle cell.** Another mechanism in which activated ROK can inactivate MLCP is via phosphorylation of another protein, CPI-17 (Eto et al., 1997). Phosphorylated CPI-17 then can directly phosphorylate MLCP, thus inactivating MLCP. **Thus RhoA and ROK promote smooth bladder contractility by inactivation of MLCP** (Fig. 110.15).

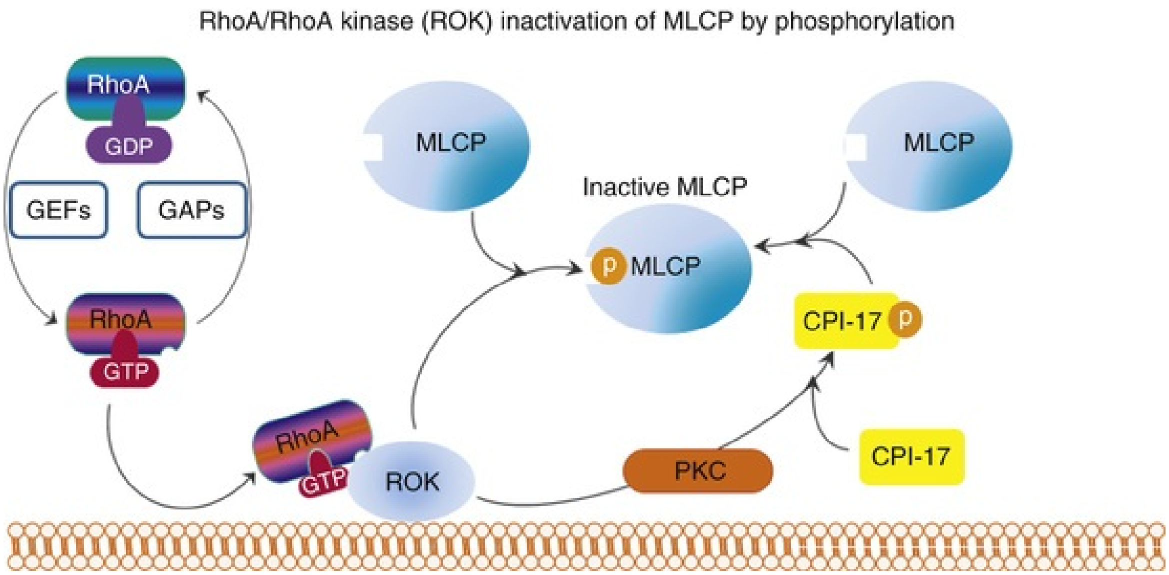

FIG. 110.15 Pathways for RhoA and Rho kinase (ROK) interaction with myosin light chain phosphatase (MLCP) in regulating smooth muscle contractility. See text for details. *GAPs,* GTPase-activating proteins; *GDP,* guanosine diphosphate; *GEFs,* guanine nucleotide exchange factors; *GTP,* guanosine triphosphate; *PKC,* protein kinase C.

Membrane Electrical Properties and Action Potentials

Smooth muscle cellular membrane potential is critical in regulating contraction because smooth muscle cells are excitable (can generate APs) and contractility is dependent on the membrane potential. One must keep in mind that studies of membrane properties of single smooth muscle cells do not take into account that the detrusor functions as a syncytium of cells involving gap junctions that allow electrical coupling among the cells. Furthermore, it is likely that in certain species, detrusor muscle interstitial cells, with their own intrinsic pacemaker activities, modulate smooth muscle cell excitability. Therefore, although single cell smooth muscle studies allow the ability to perform patch-clamp electrophysiologic experiments to study membrane properties, these findings are not necessarily reflective of the behavior of the syncytium of smooth muscle cells.

The membrane potential of a cell, in millivolts (mV), is created primarily by concentration differences between intracellular and extracellular spaces of the ions Na^+, K^+, and Cl^-. The approximate concentrations of these ions are as follows:

Ion Concentration (mEq/L)	**Na^+**	**K^+**	**Cl^-**
Intracellular	5–15 (low)	130–140 (high)	4–30 (low)
Extracellular	130–140 (high)	3–5 (low)	105–115 (high)

The equation for calculating membrane potential is determined by the Goldman-Hodgkin-Katz voltage equation, as follows:

$$Em = \frac{RT}{F} \ln\left(\frac{PNa[Na]o + PK[K]o + PCl[Cl]i}{PNa[Na]i + PK[K]i + PCl[Cl]o}\right)$$

where

Em = membrane potential
R = universal gas constant
T = absolute temperature
F = Faraday constant
PNa, PK, or PCl = permeability to that ion in arbitrary units

[…]o = concentration of that ion, outside (extracellular)
[…]i = concentration of that ion, inside (intracellular).

At rest, most cells are permeable to K^+ but impermeable to Na^+ and Cl^- (PNa and PCl = 0); thus the aforementioned equation for resting membrane potential essentially becomes the reversal potential for K^+, which is −62 mV. However, if the membrane becomes permeable Na^+ and Cl^-, the membrane potential will reflect the contribution of the electrochemical gradient of all these ions. The reversal potentials for Na^+ and Cl^- are approximately +65 mV and −85 mV, respectively. The resting membrane potential of human detrusor muscle cells varies and has been measured at −50 to −60 mV (Fry et al., 2002; Montgomery and Fry, 1992), although measurements in cultured human detrusor smooth muscle cells were more depolarized at −28 mV (Hristov et al., 2011).

Guinea pig smooth muscle cell APs were studied in detail by Klöchner (Klöchner and Isenberg, 1985). Pulse current (current passed from inside the cell to outside) via a patch electrode induced an AP, and continuous current resulted in a train of repetitive APs. The morphology of the AP tracings was typical of that of excitable cells, with four phases: phase 0, slow depolarization; phase 1, fast upstroke; phase 2, repolarization; and phase 3, hyperpolarization (Fig. 110.16). With use of voltage clamping techniques and pharmacologic channel blockers or changes in ion concentrations in extracellular buffer, the types of ionic currents that make up the phases of smooth muscle AP tracing were determined (see Fig. 110.16). Phase 1 fast upstroke of the AP is composed of a Ca^{2+} inward current (abbreviated I_{Ca}). Phases 2 repolarization and 3 hyperpolarization of AP are the result of a K^+ outward current (abbreviated I_K). These ionic currents are mediated by various ion channels.

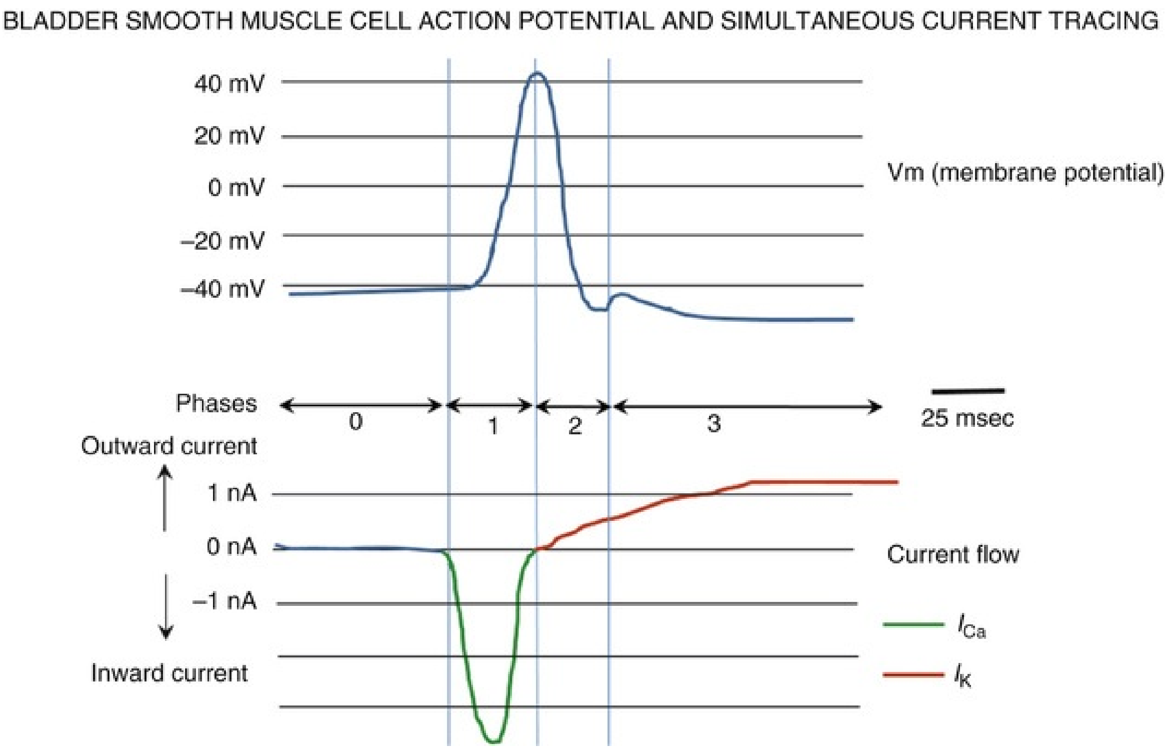

FIG. 110.16 The membrane potential *(upper panel)* and the current flow *(lower panel)* in a detrusor myocyte action potential (AP). There are four phases of the AP, and each phase is mediated by a different ionic current. Phase 0 is slow depolarization. Phase 1 is the fast upstroke of the AP mediated by Ca^{2+} inward current (I_{Ca}). Phases 2 and 3 are hyperpolarization of the AP mediated by K^+ outward current (I_K).

The I_K that occurs during phases 2 and 3 of the AP is the result of K^+ flowing out of the cell through different K^+ channels including small and large conductance calcium-activated K^+ channels (SK and BK, respectively) and voltage-gated K^+ channels (Kv) (Heppner et al., 1997; Hristov et al., 2011). **Blockage or inhibition of any of these K^+ channels would promote myocyte contractility and increase the propensity for spontaneous myocyte activity. Of these different types of K^+ channels, BK is the most critical.** BK regulates myocyte contractility by regulating the membrane potential, which in turn determines activity of the L-type voltage-dependent calcium channel (VDCC), which in turns determines $(Ca^{2+})_i$ and therefore the contractility of the myocyte.

Excitation-Contraction Coupling

When ACh, released by postganglionic parasympathetic nerve terminals, activates smooth muscle muscarinic M_3 receptors, smooth muscle intracellular Ca^{2+} concentration increases through two mechanisms: extracellular entry through VDCC L-type Ca^{2+} channels (Andersson and Arner, 2004; Andersson and Wein, 2004; Nausch et al., 2010; Schneider et al., 2004a, 2004b) and release of intracellular Ca^{2+} stores via G-protein activation with resultant inositol triphosphate (IP_3) production (Braverman et al., 2006a; Eglen et al., 1994; Fry et al., 2002; Harriss et al., 1995; Hashitani et al., 2000; Iacovou et al., 1990). Because the M_3 receptor is a canonical G_q-coupled protein (seven transmembrane domains), the downstream mechanisms after M_3 activation resulting in release of intracellular Ca^{2+} are reviewed in detail (Fig. 110.17). Other canonical receptors that share the same G_q-activated downstream mechanisms include all the odd muscarinic receptor subtypes (M_1, M_3, M_5), α_1-adrenoreceptors, angiotensin II receptors, histamine H_1 receptors, and 5-HT_2 serotonin receptors, although this is not the complete list (the 2012 Nobel Prize in Chemistry was awarded to Drs. Brian Kobilka and Robert Lefkowitz for their work in unraveling how G-coupled receptors work). Once the M_3 receptor is activated by ACh, it activates the α subunit of the G_q protein. The activated G protein then activates the membrane-bound enzyme, phospholipase C (PLC). Activated PLC cleaves a membrane phospholipid, PIP_2 (phosphatidylinositol 4,5-bisphosphate), to form cytosolic IP_3 (inositol triphosphate). IP_3 binds to its receptor at the SR, which causes stored Ca^{2+} to be released. The other product of PIP_2 cleavage is diacylglycerol (DAG), which remains membrane bound. DAG binds to protein kinase C (PKC), which is bound to the membrane, thereby activating PKC. PKC is a protein kinase that goes on to phosphorylate myriad proteins to induce secondary signals. Fig. 110.17 shows a diagram of the two categories of secondary messenger pathway that all G-coupled receptors follow: One pathway is the IP_3/PKC pathway, and the other is the cyclic adenosine monophosphate/protein kinase A (cAMP/PKA) pathway. The M_2 receptor subtype is coupled to $G_{i/o}$ and results in increased cAMP and activation of PKA. It has been shown in transgenic animals, in which selective deletion of either M_2 or M_3 receptors is created, that M_3 is the subtype that mediates the bladder contractions in the mouse and humans (Fetscher et al., 2002; Matsui et al., 2000; Stengel et al., 2002).

The dogma that the release of intracellular stores of Ca^{2+} is the main driver for nerve-induced smooth muscle contraction has been challenged. Investigators have shown in **mouse detrusor smooth muscle that Ca^{2+} entering through L-type VDCCs is the only driver of contraction** (Nausch et al., 2010) after nerve stimulation with electric field stimulation (EFS), which causes efferent nerves to release neurotransmitters. EFS-induced smooth muscle contraction was reduced with an anticholinergic (atropine) and VDCC blocker (diltiazem), but EFS-induced contractions were not reduced by blocking IP_3-mediated signaling or inhibition of PLC. In this study, all purinergic components were blocked by using α,β-methylene ATP in the experiments, so only the muscarinic component was being studied.

Although the normal contraction in the human detrusor smooth muscle is mediated by ACh, in disease states the excitation neurotransmitter could possibly be caused by ATP. Human bladders from obstructed and OAB subjects were studied and found to have atropine-resistant contractions that were blocked by the ATP-receptor blocker α,β-methylene ATP, suggesting a purinergic excitatory component to the pathologic bladder contractions (Bayliss et al., 1999). In this study, normal human bladders had no purinergic excitation-coupling signaling. Investigations in mouse smooth bladder revealed that $P2X_1$ and M_3 receptors contribute to the muscle contractions. However, there appeared to be an element of suppression of the muscarinic excitation-contraction coupling by purinergic activation (Heppner et al., 2009). This observation supports a hypothesis of how DO (LUTS) and bladder underactivity can occur simultaneously in a patient, as with detrusor hyperactivity with impaired contractility (DHIC) (Resnick and Yalla, 1987). It has already been shown that purinergic signaling is increased in the human aging bladder (Yoshida et al., 2001). Furthermore, if the interplay between purinergic and muscarinic signaling occurs in human as it does in mice, then this increased purinergic signaling detected in elderly human bladders can explain the occurrence of LUTS and overactivity (through increased purinergic-activated afferent activity; see later) with simultaneous incomplete bladder emptying (detrusor underactivity or impaired contractility through suppression of muscarinic signaling). This describes DHIC. Furthermore, this interplay gives rise to the possibility of treating DHIC by blocking purinergic signaling.

Calcium Signaling in Detrusor Myocyte

Because contractility of the smooth muscle is dependent on Ca^{2+}, there are many control mechanisms regulating intracellular Ca^{2+}. I_{Ca} (Ca^{2+} inward current) occurring during the phase 1 fast upstroke of APs is mediated by voltage-dependent Ca^{2+} channels (gene name is *CaV* or *CACNA1*). As discussed in the previous section, Ca^{2+} entry through the VDCC is likely the main contributor to the contraction. There are several types of VDCCs, but the two types that are important in bladder smooth muscle contraction are L-type (*L* = long lasting) and T-type (*T* = transient). The classic VDCC, the L-type, which is blocked by traditional Ca^{2+} blockers such as nifedipine (a dihydropyridine), diltiazem (a nondihydropyridine), and verapamil (a phenylalkylamine), is present on smooth muscle cells and is activated by AP-induced depolarization (Nausch et al., 2010; Rivera and Brading, 2006). T-type VDCCs responded to lower magnitudes of depolarization, had smaller conductance, and have no highly specific blockers yet (Fry and Jabr, 2014). The participation of T-type VDCCs in bladder smooth muscle physiology may allow a finer control of the excitation coupling and/or be important in detrusor contractile pathologies. Calcium imaging is a technique whereby one can visualize changes in single-cell intracellular Ca^{2+} concentrations ($[Ca^{2+}]_i$) by using calcium dyes that fluoresce with intensities directly correlated with $(Ca^{2+})_i$. Calcium imaging during the course of a smooth muscle cell contraction reveals a “calcium flash” caused by a sudden large increase in $(Ca^{2+})_i$ followed by mechanical contraction with shortening of the cell. This influx of Ca^{2+} through both types of VDCC initiates the actinomyosin cross-bridge cycling as detailed in the previous section.

When $(Ca^{2+})_i$ rises via entry through VDCCs during the AP, this causes the SR to release its stores of Ca^{2+} (internal stores) through ryanodine receptors (RyRs)—a phenomenon called *calcium-induced calcium release* (CICR). Internal stores of Ca^{2+} released are visualized as “calcium sparks” (from microfluorometry) that were first discovered in arterial smooth muscle (Nelson et al., 1995). These calcium sparks activate (open) the nearby membrane-associated calcium-activated large conductance potassium channel (BK or gene name *KCNMA1*), which lets potassium out of the cell, thus hyperpolarizing the cell and relaxing the smooth muscle cell (see prior section about I_k portion of the AP and Fig. 110.16). These calcium sparks are the cause of the spontaneous transient outward currents (STOCs) of K^+ mediated by the BK channel. Calcium sparks were studied in detrusor smooth muscle (Collier et al., 2000; Herrera et al., 2001). In bladder myocytes, the calcium sparks (e.g., RyR openings) were not tightly linked to the gating of L-type VDCCs, as in cardiac myocytes, because the SR is not as physically close to the VDCC in the bladder myocytes as in the cardiac myocytes. Similar to arterial myocytes, the calcium sparks in detrusor myocytes also activate BK channels. These interactions are shown in the animation on the ExpertConsult.com.

Intracellular Ca^{2+} also activates a variety of cellular responses when it enters the cytoplasm of a cell. To be effective as a signal, its concentration must be returned to submicromolar levels, driven by ATP pumps. The Ca^{2+} pump is a membrane-bound, Ca^{2+}-activated ATPase, similar to the Na^+-K^+ pump that controls ion balance and membrane potential in all animal cells. These pumps belong to a superfamily of ATPases known as *P type*, because they depend on the autophosphorylation of a conserved aspartic acid residue using ATP. The rise in intracellular Ca^{2+} can be lowered by pumping Ca^{2+} back into the SR or mitochondria or out into the extracellular space (Fig. 110.18).

FIG. 110.18 Intracellular calcium *(green circles)* in the detrusor myocyte can be regulated by various mechanisms: (1) exchanging for Na^+ ion; (2) pumping out of cell using adenosine triphosphate (ATP); (3) pumping into sarcoplasmic reticulum (SR) with SERCA/ATP; (4) binding to calcium-binding molecule; (5) pumping into mitochondria. *ADP,* Adenosine diphosphate.

When intracellular stores of Ca^{2+} within the SR are depleted, the myocyte has a mechanism by which another type of Ca^{2+} channel (ORAI) opens, thus allowing influx of extracellular Ca^{2+} to refill the SR stores. This process is called the *store-operated* Ca^{2+} *entry* (SOCE) or capacitive Ca^{2+} entry. The sensor for

SR Ca^{2+} concentration is the protein called STIM (stromal interaction molecule) (Roos et al., 2005). When STIM senses low Ca^{2+} concentrations, STIM proteins aggregate to form discrete membrane clusters that tether the plasma membrane protein ORAI, allowing tetramers of ORAI to form a pore for extracellular Ca^{2+} entry into the cell (Penna et al., 2008). This Ca^{2+} channel composed of multiunits of ORAI is called *CRAC* (calcium release–activated channel). The electrophysiologic current measured from Ca^{2+} entry through CRAC is denoted I_{CRAC}. Although SOCE has been shown to be present in various other smooth muscles, SOCE has not been measured yet in detrusor myocytes but is likely to exist.

Propagation of Electrical Responses

Specialized proteins called **connexin 43 (gap-junction proteins)** are expressed between the membranes of connected smooth muscle cells. The basic unit (monomer) of Cx43 is composed of four transmembrane domains with the carboxy-terminal and amino-terminal intracellular (Fig. 110.19). Six monomers of Cx43 are arranged as a hexamer unit with a central pore channel. The hexameric unit Cx43 of two neighboring myocytes will have to dock to align the central pore so that ions can flow from one myocyte to another. The electrically coupled myocytes can be measured using double whole-cell patch (DWCP) electrophysiology. This technique was performed on cultured human myocytes and gap junction currents were detected; also, Western blots confirmed the presence of Cx43 (Wang et al., 2006).

(D) Patch clamp can reveal electrically coupled cells.

However, lack of fused tetanic contractions in normal detrusor smooth muscle strips suggests that there is poor electrical coupling between smooth muscle cells (Uvelius and Gabella, 1980). **Measurements of tissue impedance support the observation that the detrusor is less well coupled electrically than other smooth muscles** (Brading and Mostwin, 1989; Parekh et al., 1990). **Poor coupling could be a feature of a normal detrusor that prevents synchronous activation of the smooth muscle cells during bladder filling.** Nevertheless, some degree of coupling within a muscle bundle clearly does exist, because it is possible to measure the length constant of a bundle (Seki et al., 1992). There is also evidence for gap-junction coupling between detrusor cells in humans and guinea pigs, detected by whole-cell patch clamp recordings (Wang et al., 2006) and Ca^{2+} imaging (Neuhaus et al., 2002), respectively. Significant expression of Cx43 and Cx45 gap-junction proteins is found in human detrusor muscles (John et al., 2003; Wang et al., 2006). However, electrical couplings between detrusor cells seem to be reduced during postnatal development because coordinated, large-amplitude, low-frequency contractile activity as seen in the neonate rat bladder declines and is replaced by low-amplitude, high-frequency, more irregular activity in older rats, which appears to depend on the disruption of the intercellular smooth muscle communication (Szell et al., 2003). It has also been suggested that a change in the properties of the cell coupling may underlie the generation of the uninhibited detrusor contractions occurring in overactive and aging bladders (Brading, 1997b, 2006; Seki et al., 1992).

Detrusor Interstitial Cells

Evidence suggests that the “normal” bladder may be spontaneously active and that exaggerated spontaneous contractions could contribute to the development of DO. In a rat model for DO, local areas of spontaneous contractions are increased and more coordinated in rat bladders with partial outlet obstruction (Drake et al., 2003). However, it is still not clear which cells generate spontaneous activity in the bladder. As mentioned before, detrusor myocytes could be spontaneously active, and electrical coupling through gap junctions could trigger spontaneous contractions (Brading, 1997b, 2006). Alternatively, another population of cells in the bladder known as *interstitial cells* or *myofibroblasts* has been proposed for a pacemaking role in spontaneous activity of the bladder (Andersson and Arner, 2004; Kumar et al., 2005). Interstitial cells have been identified in the human and guinea pig ureter, urethra, and bladder body (Fry et al., 2007; Hashitani, 2006; Kumar et al., 2005).

Interstitial cells, in addition to being located in the suburothelial layer, are also found in the detrusor layer and have been shown to be spontaneously active (Kumar et al., 2005). These cells are stained for c-KIT and located along both boundaries of muscle bundles in the guinea pig bladder (Hashitani, 2006; Hashitani et al., 2004; McCloskey and Gurney, 2002). These cells can fire Ca^{2+} waves in response to cholinergic stimulation by M_3 muscarinic receptor activation and can be spontaneously active, suggesting that they could act as pacemakers or intermediaries in transmission of nerve signals to smooth muscle cells (Johnston et al., 2008; McCloskey and Gurney, 2002; Fig. 110.20). However, Hashitani et al. (2004) have also suggested that interstitial cells in the detrusor may be more important for modulating the transmission of Ca^{2+} transients originating from smooth muscle cells than for being the pacemaker of spontaneous activity because spontaneous Ca^{2+} transients occur independently in smooth muscles and interstitial cells. It has also been demonstrated that the c-KIT tyrosine kinase inhibitor imatinib (Glivec) decreased the amplitude of spontaneous contractions in the guinea pig bladder (Kubota et al., 2004, 2006) and in muscle strips from the overactive human bladder, in which c-KIT–positive cells were increased compared with normal subjects (Biers et al., 2006), suggesting that targeting these receptors expressed in intradetrusor interstitial cells may provide a new approach for treating OAB. In addition, after application of SNP (an NO donor), interstitial cells throughout the bladder, but not detrusor muscle cells, demonstrate cGMP immunoreactivity (Gillespie et al., 2004; Smet et al., 1996). Thus increased levels of cGMP found in interstitial cells by using phosphodiesterase-5 (PDE5) inhibitors, for example, may diminish synchronicity between detrusor muscle bundles (Hashitani, 2006). These cells are also a source of prostaglandin E_2 (PGE_2) because of their expression of cyclooxygenase (COX) and a reduction in spontaneous activity of bladder muscle strips by use of PGE_2 receptor (EP) antagonists in rabbits (Collins et al., 2009).

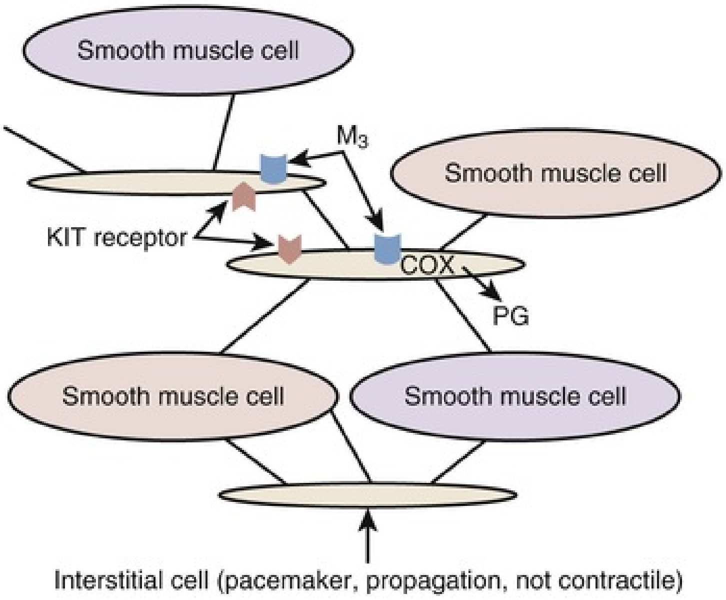

FIG. 110.20 Schematic representation of interstitial cells in the detrusor muscle layers. These cells are not contractile but may be pacemakers with spontaneous activity and propagate signals between detrusor muscles. They also express KIT receptors and muscarinic M_3 receptors, and can produce prostaglandins (PG), such as PGE_2, through activation of

cyclooxygenase (COX).

Investigators have found a new class of intradetrusor cells with pacemaker-like properties (Koh et al., 2012; Lee et al., 2014). These cells were not c-KIT positive, but rather expressed platelet-derived growth factor receptor (PDGFR)-α. The reason these investigators searched for this type of cell in the bladder was because the PDGFR-α–positive cells in the gastrointestinal tract have been found to inhibit neurotransmission in the myenteric neural plexus (Cobine et al., 2011; Kurahashi et al., 2011). Although purines such as ATP induce initial contraction of the bladder muscle (see the section on excitation-contraction coupling), there is also a prolonged relaxation that could be related to the suppression of the muscarinic excitation-coupling (Heppner et al., 2009). However, investigators found that the detrusor PDGFR-α cells, through $P2Y_1$ signaling, were the reason for the prolonged relaxation induced by purines (Lee et al., 2014). These investigators theorized that a “dual receptive field”—an excitatory field via $P2X_1$ on the smooth muscle and one inhibitory field via $P2Y_1$ on the PDGFR-α cells—provides finer regulation of detrusor contractility.

Further research is required to fully understand the role of suburothelial and intradetrusor interstitial cells and their contribution to spontaneous contractions or DO.

Key Points: Smooth Muscle Mechanics

- Muscarinic receptors induce detrusor contraction in response to ACh released from parasympathetic nerve terminals by calcium entry through Ca^{2+} channels.
- Although calcium serves the same triggering role in all muscle types, the mechanism of activation is different in smooth muscle. The contractile response is slower and longer lasting than that of skeletal and cardiac muscle.
- Evidence suggests that the “normal” bladder may be spontaneously active and that exaggerated spontaneous contractions could contribute to the development of an OAB. A population of cells within the detrusor layer, known as *interstitial cells* or *myofibroblasts*, has been proposed to have a pacemaking role in spontaneous activity of the bladder.

Bladder Mechanics

Urinary Storage (Filling)

During urine filling of the bladder, the viscoelastic behavior of the bladder depends on neuromuscular and mechanical properties. Mechanical properties are extremely sensitive to tissue structure and composition of the bladder wall. **In addition to smooth muscle, the human bladder is composed of roughly 50% collagen and 2% elastin. With injury, obstruction, or denervation, collagen content increases** (Macarak and Howard, 1999). When contractile protein content exceeds collagen, greater distensibility is achieved (compliance). **Conversely, when collagen levels increase, compliance falls.** The changes in the thickness of the lamina propria and the detrusor are mechanical requirements for the bladder to accommodate increasing urine volume. During filling, the lamina propria thins at a faster rate than the muscle wall. It has been proposed that bladder wall thinning during filling is the result of a rearrangement of the muscle bundles and also alteration of collagen coil structure (Macarak and Howard, 1999). A combination of muscle and connective tissue spatial changes is required to accommodate urine at low intravesical pressures (Chang et al., 1999). During filling, the detrusor reorganizes and muscle bundles shift position from a top-to-bottom to a side-to-side configuration. During reorganization, the coiled type III collagen fibers connecting the muscle bundles orthogonally become extended, longer, and taut and assume an orientation such that the fibers become oriented parallel to the lumen.

Bladder compliance *(C)* is defined as the change in volume *(V)* relative to the corresponding change in intravesical pressure *(P):*

$$C = DV/DP$$

Filling the bladder at a slow physiologic rate maintains an intravesical pressure of less than 10 cm H_2O (Klevmark, 1974). However, the compliance of the bladder is dependent on the rate at which fluid is instilled into the bladder (Coolsaet, 1985). This phenomenon can be seen in urodynamics when the intravesical pressure can drop when filling is slowed or stopped. The pressure-volume curve during filling of the bladder is dependent on several factors including (1) collagen, elastin, and smooth muscle as passive structures; (2) active properties of the smooth muscle; and (3) geometry of the bladder. Therefore, when there is decreased compliance of the bladder (steep filling curve), it may be the result of multiple factors including (1) fast filling rate; (2) change in composition of the bladder wall (e.g., more collagen, less elastin); (3) hyperactivity of the smooth muscle; and (4) a combination of any of these factors. The compliance of a typical bladder in 559 women with stress incontinence was measured with standardized urodynamics (50 mL/min filling rate). The data showed that the mean maximum cystometric capacity (MCC) was 392 mL; intravesical pressure (Pdet) rose from 2 cm H_2O at the beginning of fill to 6 cm H_2O at MCC (Nager et al., 2007).

Acute spinal transection of the bladder did not alter bladder compliance, although pelvic nerve transection did decrease compliance (Langley and Whiteside, 1951). **However, animal studies have suggested that central neural input is required for bladder compliance and that this is an active afferent neural process** (Smith et al., 2012b). These investigators theorized that afferent signals arising from the bladder wall during filling of the bladder are relayed to the CNS, which in turn inhibits spontaneous smooth muscle contractility, thus maintaining high bladder compliance during filling. In other words, the nervous system, in addition to viscoelastic properties of the bladder wall, has a role in maintaining bladder compliance during filling.

The bladder muscle has a broad length-tension relationship, allowing tension to be developed over a large range of resting muscle lengths (Uvelius and Gabella, 1980). The tissue shows viscoelasticity that influences muscle tension and manifests as total bladder wall tension (Venegas, 1991). Isolated detrusor strips show spontaneous mechanical activity to a variable extent. It is more frequently seen in bladders from small mammals (Sibley, 1984) but can also be seen in muscle strips from human detrusor. However, spontaneous fused tetanic contractions, such as those commonly seen in smooth muscles from the gastrointestinal tract and uterus, are almost never seen in normal bladders.

Voiding Mechanics

Intravesical pressure reflects the combined factors of abdominal (Pabd) and detrusor (Pdet) pressures. Therefore

$$Pdet = Pves - Pabd$$

Micturition relies on a neurally mediated detrusor contraction, causing Pdet to rise without a significant change in Pabd. To assess the strength of a detrusor contraction, Pdet alone is an insufficient measure. A muscle can use energy either to generate force or to shorten its length. Because the bladder is a hollow viscus, the force developed contributes to Pdet, whereas the velocity of shortening relates to urine flow (Q). There is a trade-off between generating Pdet and urine flow. This has been reviewed by Griffiths (1988). **If urethral resistance is low, as in women with sphincter insufficiency and even in normal continent women, Pdet may be almost undetectable; however, these women with modest Pdet would have normal flow rates.** In a population of 384 stress-incontinent women, the mean Pdet at Qmax on pressure-flow urodynamics study was 19 cm H_2O (Nager et al., 2007). In a group of 30 healthy men who underwent ambulatory urodynamics, Pdet at Qmax ranged from 60 to 70 cm H_2O (Schmidt et al., 2004). **The trade-off between Pdet and Q resembles a curve for constant mechanical power (W) in which**

$$W = Pdet \times Q$$

The equation explains why a woman could have normal detrusor contractility and normal detrusor power despite low voiding pressure. During micturition, Pdet reflects outlet resistance. When the urethra opens widely with a high flow (Q), little Pdet is needed to achieve the work necessary to empty the bladder. **The key message is that low voiding pressure in a woman does not equate with impaired detrusor contractility; she may simply be able to open her urethra widely. Moreover, pressure-flow nomograms developed for men for diagnosis of obstruction should not be applied to women without validation.**

Motor Sensory Network in Detrusor Muscle

Based on anatomic immunohistochemical localization studies of nerve fibers in the guinea pig, Gillespie has proposed a “motor sensory” network within the detrusor muscle wall (Gillespie et al., 2006; Fig. 110.21). This network involves the presence of sensory fibers (*green* and *red lines* in Fig. 110.21) next to detrusor myocytes and intradetrusor interstitial cells. Because the detrusor has spontaneous activity (as micromotions and/or nonvoiding contractions), the spontaneous smooth muscle contractions trigger sensory signals to the host. An increase in spontaneous activity of the detrusor smooth muscle could be interpreted as an urgency episode. Certainly, this model could help explain how decreasing smooth muscle spontaneous activity (e.g., with antimuscarinics) could decrease sensory input. The effect of tolterodine (antimuscarinic) and mirabegron (β_3 agonist) in decreasing nonvoiding contractions in a partial urethral obstruction animal model has been shown (Gillespie et al., 2012). However, the investigators did not measure the pelvic afferent output to determine whether that was reduced with the reduction of the nonvoiding contractions. Bladder wall micromotions were measured in women with sensory urgency, although the sample size was small (N = 6) (Drake et al., 2005). **This motor sensory network ties in the concept that it is not easy to separate the function of the bladder organ into simple efferent and afferent activities, because these two events are inexorably linked.**

Neural Control of the Lower Urinary Tract

Peripheral Nervous System

The LUT is innervated by three sets of peripheral nerves involving the parasympathetic, sympathetic, and somatic nervous systems (Fig. 110.22). Pelvic parasympathetic nerves arise at the sacral level of the spinal cord, excite the bladder, and relax the urethra. Lumbar sympathetic nerves inhibit the bladder body and excite the bladder base and urethra. Pudendal nerves excite the EUS. These nerves contain afferent (sensory) as well as efferent axons (de Groat and Booth, 1993; de Groat et al., 1993; Sugaya et al., 1997; Wein, 1992; Yoshimura et al., 2008).

Sympathetic preganglionic pathways emerge from the lumbar spinal cord and pass to the sympathetic chain ganglia (SCG) and then through the inferior splanchnic nerves (ISN) to the inferior mesenteric ganglia (IMG). Preganglionic and postganglionic sympathetic axons then travel in the hypogastric nerve (HGN) to the pelvic plexus and the urogenital organs. Parasympathetic preganglionic axons that originate in the sacral spinal cord pass in the pelvic nerve to ganglion cells in the pelvic plexus and to distal ganglia in the organs. Sacral somatic pathways are contained in the pudendal nerve, which provides an innervation to the penis and the ischiocavernosus (IC), bulbocavernosus (BC), and external urethral sphincter (EUS) muscles. The pudendal and pelvic nerves also receive postganglionic axons from the caudal sympathetic chain ganglia. These three sets of nerves contain afferent axons from the lumbosacral dorsal root ganglia. *PG,* Prostate gland; *U,* ureter; *VD,* vas deferens.

Parasympathetic Pathways

Parasympathetic preganglionic neurons innervating the LUT are located in the lateral part of the sacral intermediate gray matter in a region termed the *sacral parasympathetic nucleus* (de Groat and Booth, 1993; de Groat et al., 1993, 1996; Morgan et al., 1981, 1993; Nadelhaft et al., 1980). Parasympathetic preganglionic neurons send axons through the ventral roots to peripheral ganglia, where they release the excitatory transmitter ACh (de Groat and Booth, 1993). **Parasympathetic postganglionic neurons in humans are located in the detrusor wall layer as well as in the pelvic plexus. This is an important fact to remember because patients with cauda equina or pelvic plexus injury are neurologically decentralized but may not be completely denervated. Cauda equina injury allows possible afferent and efferent neuron interconnection at the level of the intramural ganglia** (de Groat and Booth, 1993; de Groat et al., 1993, 1996).

Sympathetic Pathways

Sympathetic outflow from the rostral lumbar spinal cord provides a noradrenergic excitatory and inhibitory input to the bladder and urethra (Andersson, 1993). Activation of sympathetic nerves induces relaxation of the bladder body and contraction of the bladder outlet and urethra, which contribute to urine storage in the bladder. **The peripheral sympathetic pathways follow a complex route that passes through the sympathetic chain ganglia to the inferior mesenteric ganglia and then through the hypogastric nerves to the pelvic ganglia.**

Somatic Pathways

The EUS motoneurons are located along the lateral border of the ventral horn, commonly referred to as the *Onuf nucleus* (Fig. 110.23; Thor et al., 1989). Sphincter motoneurons also exhibit transversely oriented dendritic bundles that project laterally into the lateral funiculus, dorsally into the intermediate gray matter, and dorsomedially toward the central canal.

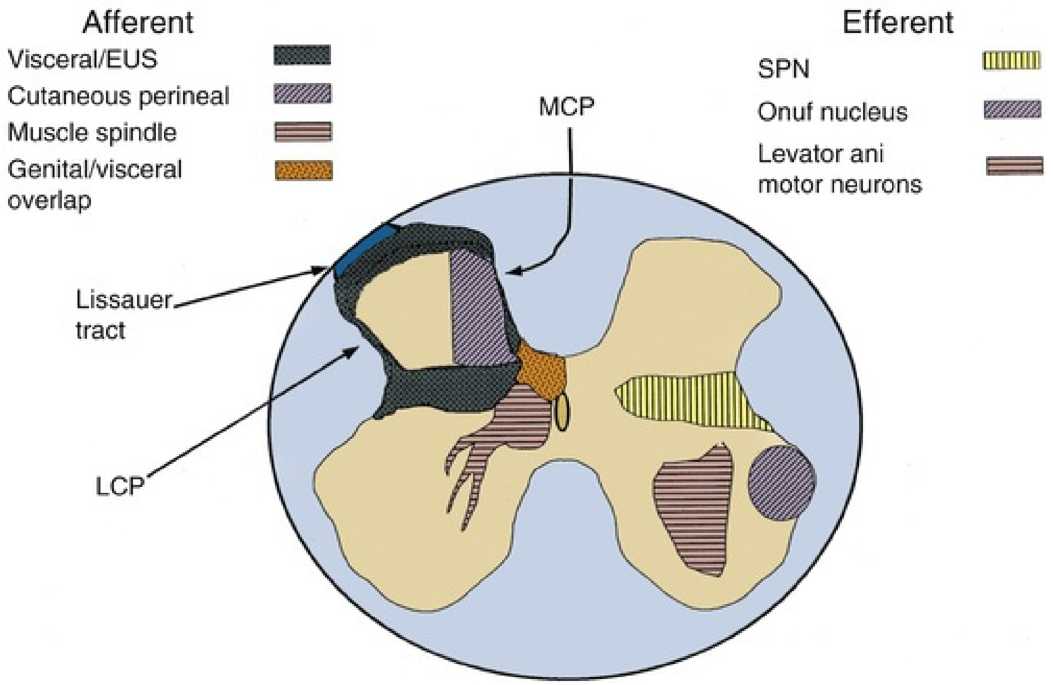

FIG. 110.23 Cross section of sacral spinal cord; neuroanatomic distribution of primary afferent and efferent components of storage and micturition reflexes. For purposes of clarity, afferent components are shown only on the left, and efferent components are shown only on the right. Both components are, of course, distributed bilaterally and thus overlap extensively. Visceral afferent components represent bladder, urethral, and genital (glans penis or clitoris) afferent fibers contained in the pelvic and pudendal nerves. Cutaneous perineal afferent components represent afferent fibers that innervate the perineal skin contained in the pudendal nerve. Muscle spindle afferent components represent Ia/b afferent fibers contained in the levator ani nerve that innervate muscle spindles in the levator ani muscle. *EUS,* External urethral sphincter; *LCP,* lateral collateral projection; *MCP,* medial collateral projection; *SPN,* sacral parasympathetic nucleus.

Afferent Pathways

Overview: Properties of Afferent Neurons.

The bladder and LUT store and evacuate urine and are controlled by a complex interaction of neural mechanisms organized by local, spinal, and brain circuits. The majority of time is spent in storage mode, during which the bladder accommodates urine and maintains continence via reflexes that prevent contraction of bladder smooth muscle and promote contraction of the urethral sphincter. This switches during micturition when the bladder contracts and the sphincter relaxes to facilitate voiding. This switch relies on sensory signals, which provide the input to the reflex circuits that control bladder filling and emptying and are also the source of nonpainful sensations of fullness and pain. Dysfunction leads to a number of disorders such as OAB syndrome and BPS/IC, with symptoms including urgency, pain, and urinary incontinence. Currently available therapeutic approaches are aimed primarily at reducing bladder contraction to relieve intravesical pressure and maintain continence. Interest in bladder afferent signaling has been driven by the realization that symptoms are a feature of dysregulated storage sensations rather than exaggerated contractile responses and therefore targeting afferent mechanisms may be a rational approach to treatment.

Pathways to the Spinal Cord.

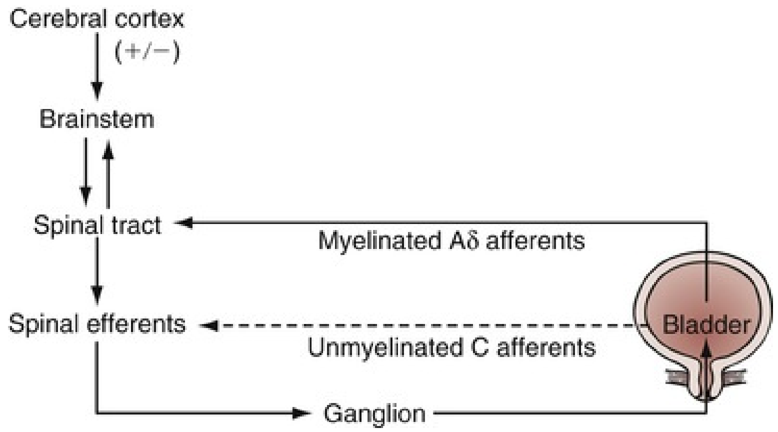
Afferent fibers innervate the LUT via pelvic, hypogastric (lumber splanchnic), and pudendal nerves. These nerves are mixed nerves that also contain the efferent parasympathetic, sympathetic, and motor fibers supplying the bladder, urethra, and sphincters. Axonally transported dyes taken up by afferent nerves are transported to the afferent cell bodies in the lumbosacral dorsal root ganglia (DRG) and the afferent terminations in the dorsal horn of the spinal cord. The primary afferent neurons of the pelvic and pudendal nerves are contained in sacral DRG, whereas afferent innervation in the hypogastric nerves arises in the rostral lumbar DRG. The central axons of the DRG neurons carry the sensory information from the LUT to second-order neurons in the spinal cord (De Groat, 1986; de Groat et al., 1996; Morgan et al., 1981; Thor et al., 1989). These second-order neurons provide the basis for spinal reflexes and ascending pathways to higher brain regions involved in micturition, continence, and mediation of sensation.

Pelvic nerve afferents, which monitor the volume of the bladder and the amplitude of the bladder contraction, consist of myelinated (Aδ) and unmyelinated (C) axons (Table 110.2, Fig. 110.24). During neuropathic conditions (spinal cord injury) and possibly inflammatory conditions, there is recruitment of C fibers that form a new functional afferent pathway that can cause urgency incontinence and possibly bladder pain (Fig. 110.25).

TABLE 110.2

Bladder Afferent Properties

FIBER TYPE	**LOCATION**	**NORMAL FUNCTION**	**INFLAMMATION EFFECT**
	Smooth muscle	Sense bladder fullness (wall tension)	Increase discharge at lower pressure threshold
C fiber (unmyelinated axons)	Mucosa	Respond to stretch (bladder volume sensors)	Increase discharge at lower threshold
C fiber (unmyelinated axons)	Mucosa muscle	Nociception to overdistention	Sensitive to irritants
		Silent afferent	Become mechanosensitive and unmask new afferent pathway during inflammation



Cerebral cortex
(+/−)
Brainstem
Spinal tract
Myelinated Aδ afferents
Spinal efferents
Unmyelinated C afferents

Ganglion

FIG. 110.24 Illustration depicting the predominant Aδ afferent contribution to the normal micturition reflex. C-fibers *(dotted line)* are normally silent unless turned on by pathology.

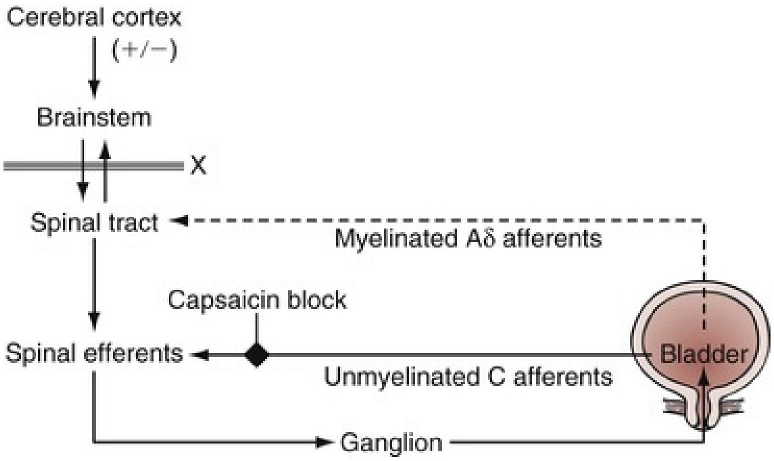

FIG. 110.25 Illustration depicting the switch in afferent contribution to the micturition reflex from Aδ-fiber predominant to C-fiber predominant with neurologic diseases, aging, and possibly inflammatory disease. Note that capsaicin (and other vanilloids) can block the C-fiber contribution under these conditions.

There is great interest in understanding the nature and origins of bladder sensation. “Sensing” bladder volume is of particular relevance during bladder storage. Nathan (1956) described the sensations of awareness and desire to micturate involving bladder distention (stretch) and contraction and suggested that these could be mapped to the urinary bladder. In contrast, the sensation of imminent micturition may originate not in the urinary bladder, but rather from the urethra. Ideas have been promulgated that link bladder filling with episodic bursts of sensation (correlating with afferent discharge) that increase in intensity during filling, with the final episodes being the most intense and often described as “urgency” (Chapple and Wein, 2005). Afferent discharges that occur during a bladder contraction have an important reflex function and appear to reinforce the central drive that maintains the detrusor contraction. Afferent nerves that respond to distention and contraction—that is, “in-series tension receptors”—have been identified in the pelvic and hypogastric nerves of cats and rats (Floyd et al., 1976; Iggo, 1955; Morrison, 1997). Afferents that respond only to bladder distention have been identified in the rat bladder (Morrison et al., 1998) and appear to be volume receptors, possibly sensitive to stretch of the urothelium. In the cat bladder, the presence of in-series tension receptors has also been reported (Downie and Armour, 1992). In the rat, there is evidence that many C bladder afferents are stretch receptors that do not respond to bladder contractions, a property that distinguishes them from in-series tension receptors (Morrison et al., 1998).

Functional Properties of Bladder Afferents.

In the human bladder, ultrastructural studies have identified only unmyelinated nerves in the urothelium and immediate suburothelial layer, with small myelinated nerves being closely associated with the smooth muscle layers (Wiseman et al., 2002). The plexus of afferent nerves in the lamina propria is thickest in bladder neck and in the initial portion of the urethra and becomes progressively less dense in adjacent regions such that the cranial region of the bladder has no afferent axons. In contrast, the afferent innervation of the musculature is more uniform throughout the bladder.

Recording from bladder afferents has revealed the diversity of afferent populations described earlier based on morphology, receptive field site, mechanical and chemical sensitivity, and electrophysiologic characteristics. **Conduction velocity measurements confirm the predominance of fibers conducting APs in the Aδ and C-fiber range. The majority of these fibers are mechanosensitive, responding with a range of thresholds from volumes that would be encountered under normal bladder filling to extreme levels of distention that would be considered noxious and give rise to pain.** Those with lower activation thresholds have small myelinated axons, whereas unmyelinated fibers in general have higher thresholds for activation. In addition, other afferents do not respond to bladder filling but can be activated by intraluminal chemicals such as hypertonic saline, capsaicin, or ATP, suggesting they may function as chemoreceptors. Still other subpopulations may be so-called silent afferents that have been described elsewhere, including the gastrointestinal tract. These afferents can be sensitized during inflammation, suggesting a role in signaling pain.

In the mouse pelvic nerve, four classes of bladder afferents (serosal, muscular, muscular/urothelial, and urothelial) have been identified based on responses to receptive field stimulation with different mechanical stimuli, including probing, stretch, and stroking the urothelium. Low-threshold, representing 65% to 80% of the total population, and high-threshold stretch-sensitive muscular afferents are present (Daly et al., 2007; Xu and Gebhart, 2008). The muscular afferents can be sensitized by application of a combination of inflammatory mediators (bradykinin, serotonin, prostaglandin, and histamine at pH 6.0) (Xu and Gebhart, 2008).

A series of studies have used open-sheet preparations of guinea pig bladder to examine the diversity of bladder afferents and to attempt to correlate structure with function. Low-threshold afferents have terminals in the muscle, described as “antenna-like” endings, and are referred to as *stretch-sensitive muscular mechanoreceptors* (Zagorodnyuk et al., 2006, 2007). These afferents, termed *tension receptors*, also respond to contraction of the detrusor muscle as well as tension generated by elongation during stretch and shortening during contraction. High-threshold afferents are also likely to terminate in the deeper muscle layers or in the serosa. These mechanosensitive endings have receptive fields (located by mechanical probing) associated with blood vessels. Thus high-threshold afferents respond to high levels of bladder stretch but may also become sensitized in response to inflammation.

Species differences, as well as differences in nomenclature, may account for some of the variations in reported properties of bladder afferents. For example, the conduction velocity that differentiates Aδ and C fibers is 2 m/sec in the cat, whereas it is 1.3 m/sec in the rat (Waddell et al., 1989). In the cat, bladder Aδ afferents appear to be low-threshold mechanoreceptors (Habler et al., 1993), whereas bladder C afferents (Habler et al., 1990) are, in general, mechano-insensitive (“silent C fibers”) (see Table 110.2). Some of the latter may be nociceptive and found to be sensitized by intravesical administration of chemicals (such as high potassium), low pH, high osmolality, and irritants such as capsaicin (Maggi et al., 1987; McMahon and Abel, 1987; Wen and Morrison, 1995; Zagorodnyuk et al., 2009; Fig. 110.26). After exposure to these substances, the sensitivity of bladder mechanoreceptors to distention increases, and some silent afferents become mechanoreceptive.

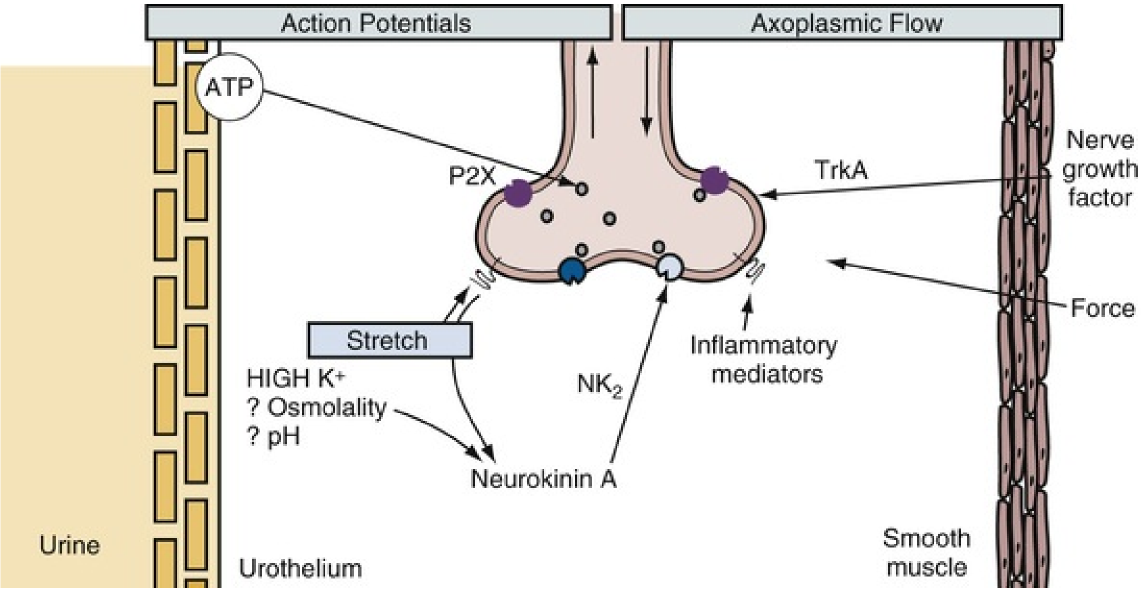

FIG. 110.26 Actions of chemical mediators that may sensitize

mechanosensory nerve endings in the bladder mucosa. Adenosine triphosphate (ATP) can be released from the urothelium and may sensitize the mechanoreceptors, which respond to stretch of the mucosa during bladder distention. P2X is the purinergic receptor subtype that binds ATP. Neuropeptides transported to the sensory ending by axoplasmic transport may be released during distention and chemical stimulation, and neurokinin A can act on NK_2 autoreceptors, which sensitize the mechanosensitive endings. This mechanism can be induced by high urinary potassium concentrations and possibly by other sensitizing solutions within the bladder lumen, such as those with high osmolality or low pH; the presence in the tissues of inflammatory mediators may also sensitize the endings. The smooth muscle can generate force that may influence some mucosal endings, and the production of nerve growth factor is another mechanism that can influence the mechanosensitivity of the sensory ending through the tyrosine kinase (TrkA) receptor.

The bladder neck and proximal urethra contain the largest density of bladder nerves (Gabella and Davis, 1998; Yokokawa et al., 1985). In the urethra, afferent nerves have been reported between the muscle fibers, surrounding blood vessels, within the urothelium, and in a dense suburothelial plexus (Crowe et al., 1986; Fahrenkrug and Hannibal, 1998; Tainio, 1993). The striated sphincter muscle surrounding the urethra receives a very sparse afferent innervation that is localized primarily to nerve bundles passing between the muscle bundles. Specialized tension receptors (muscle spindles) that are innervated by large-diameter myelinated group IA afferents and that are prominent in most striated muscles are absent (Gosling et al., 1981) or are present in low density (Lassmann, 1984) in striated sphincter muscles.

Afferent nerves may extend in some species to the luminal surface of the urothelium. In contrast, the urethral epithelium is likely to be part of a signaling system involving projections of neuroendocrine cells, interstitial cells, and sensory nerve endings. There is speculation that these urethral-neuroendocrine cells (often termed *paraneurons*) (Hashimoto et al., 1999) could release mediators such as neuropeptides or serotonin, which via activation of adjacent sensory nerves can stimulate urethral reflexes. Such types of cells are not unlike those in other types of epithelia, such as the trachea, in which a cell type termed *brush cells* has been described, which are likely chemoreceptive and make contact with nearby sensory nerve fibers (Saunders et al., 2013). In addition, there are also reports that have identified and characterized functional properties of sacral afferents responding to flow through the urethra (Snellings et al., 2012). These are important observations whereby properties of these flow-responsive afferents seem to parallel those of cutaneous afferents. This could be important in terms of restoration of bladder emptying after spinal cord injury.

Modulators of Afferent Sensitivity.

A number of parameters including stimulus-response function can be used to define the features of the various subpopulations of afferents that supply the LUT. The relationship between stimulus and response can be altered or modified according to the mechanical and chemical environment of the sensory ending. For example, bladder contractions can distort the afferent ending, whereas connective tissue elements will transmit or dissipate stimulus energy within the tissue, determining whether a response is rapidly or slowly adapting to maintained stretch. Similarly, a number of chemical mediators released from a variety of cells within the bladder wall, such as the urothelium and underlying lamina propria, will influence afferent firing.

Many mediators are released during inflammation, injury, and ischemia, as well as from a number of cell types such as mast cells, fibroblasts, and neurons. Some mediators act directly on sensory nerve terminals, whereas others act indirectly, causing release of yet other agents from nearby cells. Thus this can lead to augmented sensitivity of nerve endings to mechanical and chemical stimuli and may also contribute to chronic pain states. Examples of local mediators include neurotrophins, purines, proteases, prostanoids, and cytokines. They produce their effects on visceral afferent nerves by three distinct processes. First, they can act directly, by opening ion channels on the nerve terminals. Second, they can sensitize endings without causing direct stimulation but causing hyperexcitability to other chemical and mechanical stimuli. Third, as is the case with neurotrophins, they can change the phenotype of the afferent nerve over long periods. For example, they may alter expression of channels, receptors, or mediators in the sensory neuron (Vergnolle, 2008). The result of sensitization is a leftward shift in the stimulus-response function. This means that for any given level of stimulation, a greater afferent barrage is generated. Peripheral sensitization normally develops rapidly and is relatively short lived. However, in the presence of maintained injury or inflammation, the sensitization can be prolonged by changes in gene expression. Genes influenced in this way include those that determine the amount and pattern of neurotransmitter release by central nerve terminals in the brain and spinal cord. This alters the way that sensory signals are processed within the CNS and contributes to central sensitization (Woolf, 2011).

In contrast, ineffective or inefficient bladder emptying may be caused by several changes including damage or injury to bladder (afferent) pathways. Although mechanisms underlying detrusor underactivity are not well explored or defined, conditions including diabetes mellitus, classically referred to as a *diabetic cystopathy,* have been linked with impaired sensory function and increased residual urine (Ellenberg, 1980; Xiao et al., 2013). Factors including ischemia, altered glucose metabolism, and/or free radical formation may play a role in diabetic neuropathy and decreased sensation. Studies in aged rats have revealed a decreased afferent sensitivity to changes in bladder volume and a decreased level of afferent neuropeptide expression (Hotta et al., 1995; Mohammed and Santer, 2002). Also, studies in humans have revealed an age-related decreased response to bladder filling in brain regions that play a role in bladder sensation (Griffiths et al., 2007). Therefore **decreased afferent sensitivity or excitability in a number of conditions in addition to normal aging may be an important factor leading to impaired voiding** (Miyazato et al., 2013; Smith, 2010).

Nitric Oxide.

NO has been identified as a **major inhibitory transmitter mediating relaxation of the urethral smooth muscle during micturition** (Andersson, 1993; Andersson and Persson, 1995; Andersson et al., 1992; Bennett et al., 1995). In addition, **NO is also involved in controlling bladder afferent nerve activity.** Inhibitors of NOS, given systemically or intrathecally, do not affect normal micturition in conscious or anesthetized rats. However, DO that accompanies irritation is ameliorated by spinal application of NOS inhibitors (Kakizaki and de Groat, 1996; Lagos and Ballejo, 2004; Rice, 1995). Aizawa et al. (2011) examined the effect of NO on sensory signaling by directly recording afferent activity arising from the bladder in vivo. Release of NO can be inhibited using nonmetabolizable analogues that compete with L-arginine as substrate for NOS. On such inhibitor, L-NAME, increased the afferent response to bladder filling by about 50%, which was reversed by activation of NO pathways with L-arginine. These data suggest that **NO is able to inhibit afferent activity,** an observation consistent with earlier cystometric analysis of the effect of activating the NO pathway (Ozawa et al., 1999). In addition to studying NO mechanisms in the normal bladder, Aizawa et al. also showed that application of L-arginine significantly inhibited hypersensitivity induced by the cyclophosphamide metabolite acrolein, which is used experimentally as a model for BPS/IC.

The actions of NO are mediated through elevation of the intracellular

second messenger cGMP (Fig. 110.27). The second messengers cAMP and cGMP are synthesized from the corresponding nucleoside triphosphates by their respective membrane-bound or soluble adenylate or guanylate cyclases. cAMP and cGMP are inactivated by phosphodiesterases (PDEs) by hydrolytic cleavage of the 3′-ribose phosphate bond. Therefore **the level of intracellular second messengers can be regulated by PDE isoenzymes** (Truss et al., 1999, 2001). For example, PDE5 terminates the action of NO, and PDE inhibitors can be used therapeutically to prolong the action of NO at a number of sites including the bladder, prostate, and blood vessels. Behr-Roussel et al. (2011) found that inhibition of PDE5 attenuated bladder afferent activity in a rat model of spinal cord injury. Thus, in addition to an important role for PDEs in regulation of smooth muscle tone, available data suggest that these agents may represent a target for treatment of hypersensitivity disorders of the bladder such as BPS/IC and OAB.

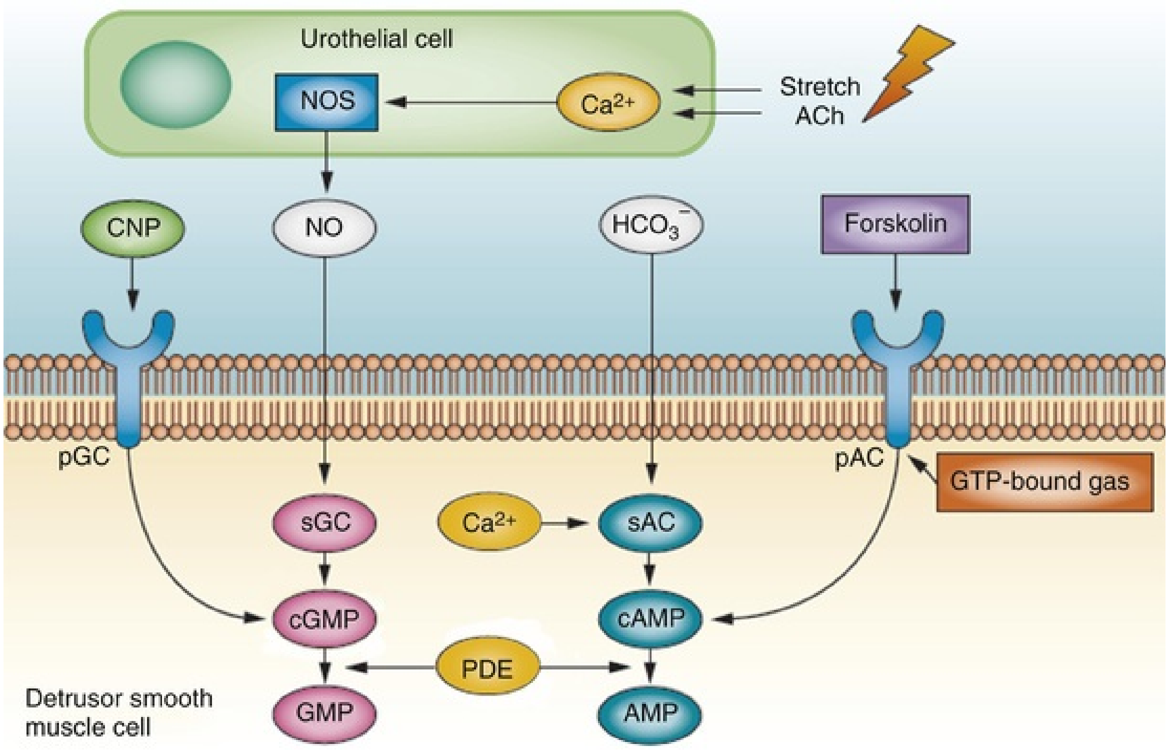

FIG. 110.27 Schematic diagram of the cyclic nucleotide signaling pathways. Stretch stimuli, or acetylcholine (ACh) release, increase internal Ca^{2+} levels in nitric oxide synthase (NOS)–expressing urothelial cells. NOS produces nitric oxide (NO), which signals to detrusor smooth muscle cells. NO is thought to have a modulatory role in the lower urinary tract, including the relaxation of urethral smooth muscle, modulation of neurotransmitter

release from efferent nerves, regulation of urothelial permeability, and modulation of afferent nerve activity. Moreover, a pathophysiologic role of NO has been suggested because injury or chronic inflammation can upregulate the expression of inducible NOS. Guanylyl cyclases located in the cytoplasm or plasma membrane synthesize cyclic guanosine monophosphate (cGMP) in response to NO or C-like natriuretic peptide (CNP), respectively. Cyclic adenosine monophosphate (cAMP) is synthesized by adenylyl cyclases, either associated with G protein–coupled receptors in the plasma membrane or in the cytoplasm. Membrane-associated adenylyl cyclases are activated by guanosine triphosphate (GTP)–bound $G_s\alpha$ and forskolin, whereas cytoplasmic adenylyl cyclases are regulated by HCO^{3-} and Ca^{2+} but insensitive to forskolin or activated $G_s\alpha$. cAMP and cGMP are hydrolyzed to AMP and GMP, respectively, by phosphodiesterases (PDEs). *pAC,* Particulate (plasma membrane) adenyl cyclase; *pGC,* particulate (plasma membrane) guanylyl cyclase; *sAC,* soluble (cytoplasmic) adenyl cyclase; *sGC,* soluble guanylyl cyclase. (From Rahnama'i MS, Ückert S, Hohnen R, et al.: The role of phosphodiesterases in bladder pathophysiology. *Nat Rev Urol* 10:414–424, 2013.)

Purinergic Signaling.

It is well established that the urothelium releases ATP in response to stretch and that this acts in a paracrine fashion to influence the function of myofibroblasts and bladder afferent nerves (Fig. 110.28). $P2X_2$ and $P2X_3$ receptors are expressed on unmyelinated afferent fibers innervating the bladder, and thus the hypothesis has been put forward that mechanosensitivity, at least in those afferents in proximity to the urothelium, involves ATP release by stretch and activation of $P2X_2$ and $P2X_{2/3}$ receptors on the afferents (Ferguson et al., 1997; Vlaskovska et al., 2001). In the normal bladder, it is believed that a balance between the excitatory effects of ATP and inhibitory effects of NO may determine micturition thresholds and urinary frequency and that this balance may be disturbed in bladder disorders. Elevated ATP levels have been demonstrated in patients with DO and BPS/IC (Kumar et al., 2007). Munoz et al. (2010), using a rat model of DO (diabetic bladder), found increased levels of ATP but normal levels of NO. Conversely in an underactive bladder model induced by chronic sugar intake, NO levels were increased whereas ATP remained normal. This suggests that the balance between ATP and NO is altered in bladder dysfunction.

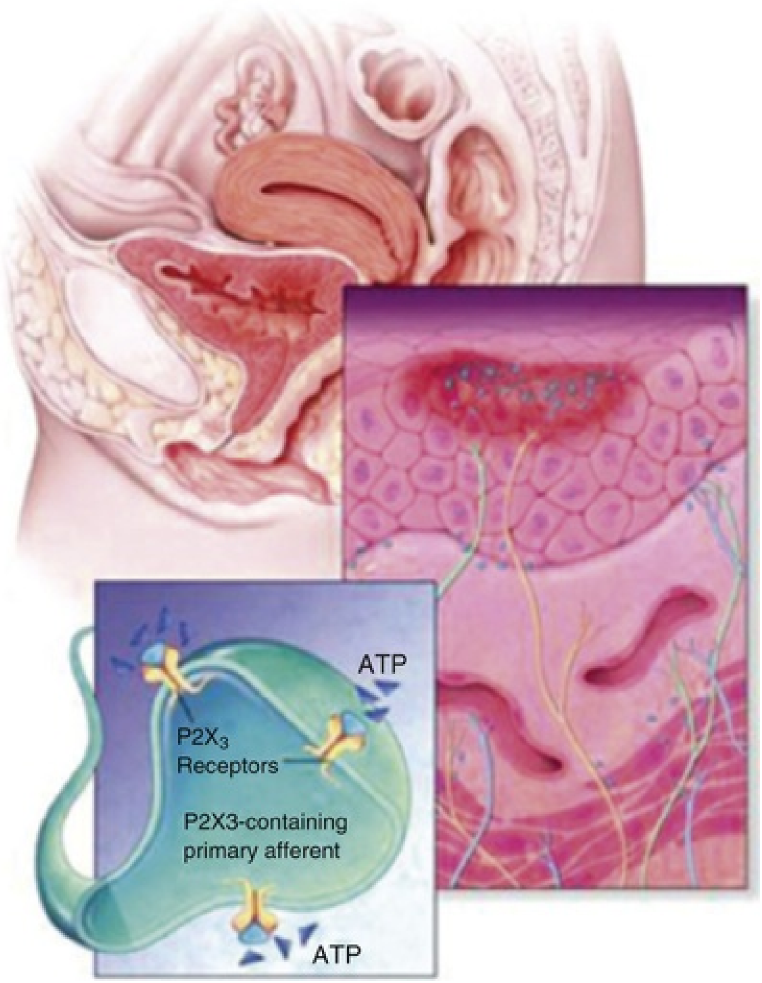

FIG. 110.28 Morphology and wiring of the lower urinary tract (LUT). In the LUT, adenosine triphosphate (ATP) (shown as *blue triangles*) is present in large extracellular concentrations, is released by various cells including epithelia, fibroblasts, and smooth muscles, and can activate C-fiber afferent and promote sensitization. Release of ATP is augmented in conditions of stress, injury, inflammation, and infection. (From Ford AP, Undem BJ: The therapeutic promise of ATP antagonism at P2X3 receptors in respiratory and urological disorders. *Front Cell Neurosci* 7:267, 2013.)

Transient Receptor Potential Cation Channels.

A number of different members of the transient receptor potential (TRP) channel family are expressed in the bladder, mostly in association with sensory nerve fibers involved in mechanotransduction and nociception. TRPV1, TRPV2, TRPV4, TRPM8, and TRPA1 are expressed in varying levels within the bladder. TRPV1, the most extensively studied TRP channel, is expressed on capsaicin-sensitive afferent pathways, predominantly C-fiber nociceptors, and responds to increases in temperature to the noxious range (>43°C) and to protons, suggesting that it functions as a transducer of painful thermal stimuli and acidity in vivo. Thus C fibers signal inflammatory or noxious events in the bladder. TRPV1 has been shown to play an integral role in modulating the excitability of bladder afferents and the generation of hypersensitivity, induced by bladder inflammation (Apostolidis et al., 2005a; Birder et al., 2002). It is through desensitization of this receptor that agents such as resiniferatoxin (RTX) act to treat symptoms in OAB (Kissin and Szallasi, 2011). TRPV1 is predominantly expressed on sensory nerves and has been identified within nerve plexuses running in the muscle layer and suburothelium as well as within the urothelium.

RTX is the principal active ingredient in the drug euphorbium, which is derived from the air-dried latex (resin) of the cactus-like plant *Euphorbia resinifera*. In 1975 the principal active ingredient in euphorbium was isolated and named *resiniferatoxin* (Hergenhahn et al., 1975). In 1989, RTX was recognized as an ultrapotent analog of capsaicin; however, it has unique pharmacologic effects as well (Szallasi and Blumberg, 1990), such as desensitization without prior excitation of the pulmonary chemoreflex pathway (Szolcsanyi, 1990). In patients with spinal cord injury–induced DO, clinical response to intravesical therapy with RTX showed changes in nerve fiber staining as well as marked improvements on cystometry and other parameters (Brady et al., 2004). Furthermore, it has also been shown that intravesical application of high-dose capsaicin as well as RTX is effective for treating painful symptoms in IC patients (Lazzeri et al., 1996, 2000), although a prospective, randomized clinical trial using intravesical RTX application showed no effect in patients with IC (Payne et al., 2005).

TRPV4 is a member of vanilloid TRPV channels and a nonselective cation channel activated by mechanical pressure, osmolarity (hypotonicity), moderate warmth (>27°C), and chemical stimuli such as phorbol esters. Interest in TRPV4 has been fueled by the observation of impaired voiding behavior in knockout mice (Gevaert et al., 2007). This channel shows mechanosensitivity and is proposed to play a role in the micturition reflex by activating C-fiber afferents (Aizawa et al., 2012). However, the site of action of TRPV4 agonists may in fact be the urothelium, which expresses the TRPV4 channel (Birder et al., 2007a), particularly in association with adherence junctions, where they may be preferentially activated by stretch and lead to the release of ATP (Yamada et al., 2009). Inhibition of TRPV4 has been shown to improve symptoms in a model of experimental cystitis (Everaerts et al., 2010).

TRPA1 is the only member of the ankyrin TRP channel and a receptor for several pungent chemicals that evoke pain, such as allyl isothiocyanate (the pungent compound in mustard oil), allicin (garlic), cinnamaldehyde (in cinnamon), and acrolein (a metabolite of cyclophosphamide). TRPA1 also functions as a receptor-operated channel that can be activated by growth factors or proinflammatory peptides such as bradykinin, which increases intracellular Ca^{2+} levels using G protein–coupled receptors. TRPA1 is also expressed in the bladder and is particularly associated with C-fiber endings in the suburothelium that co-localize calcitonin gene–related peptide (CGRP). Agonists acting at the receptor cause bladder overactivity and are suggested to play a role in mechanotransduction and in signaling pain. TRPA1 has also been demonstrated in the urothelium at transcriptional and protein levels. Expression is increased in a spinal cord injury model, and pharmacologic blockade and RNA knockdown of TRPA1 were effective in normalizing bladder reflex function (Andrade et al., 2011).

TRPM8 is a member of the temperature-sensitive TRP channels that responds to cold temperature of less than 23°C. Pharmacologic agents that evoke cool sensation, such as menthol and ilicin, can activate TRPM8. Interest in its role in the bladder stems from the observation that instillation of cold saline into the bladder elicits a contractile response (at pressures or volumes below the threshold for normal voiding). This response to a cooling stimulus (which has been referred to as the *bladder cooling reflex*) was originally thought to indicate a supraspinal neurologic lesion, and the test (termed the *ice-water test*) has been used in the diagnosis of bladder disorders such as OAB and BOO (Chai et al., 1998). Expression of TRPM8 has been identified on bladder afferent fibers and on the cell bodies in the DRG, where it co-localizes with nociceptive markers such as CGRP and IB4 (Hayashi et al., 2009a). Previously Lashinger et al. (2008) showed that application of a TRPM8 channel blocker decreased voiding frequency and abdominal motor responses in the rat, suggesting that in addition to cold sensing, TRPM8 may also be involved in the afferent control of micturition and nociception.

Cannabinoids.

The multicenter Cannabinoids in Multiple Sclerosis (CAMS) study reported that the use of cannabis-based extracts significantly improved symptoms of urge incontinence and DO in patients with multiple sclerosis. This observation has provoked interest in the study of expression and function of cannabinoid (CB) receptors in the bladder. In the human bladder, both receptors could be identified in the urothelium and detrusor, where CB1 receptors were more abundant than CB2 (Tyagi et al., 2009). In patients with BPS/IC and IDO, a significant increase in nerve fibers expressing CB1 in the urothelium was observed, strongly suggesting a role for CB1 in OAB (Mukerji et al., 2010). Functional experiments also found a reduction in distention-evoked afferent firing in response to application of a CB1 agonist. In particular, high-threshold afferents typically associated with noxious stimuli were directly affected. In contrast, Gratzke et al. (2009) found CB2 receptors predominated in the urothelium and suburothelium and on sensory nerve fibers and found that CB2 agonists inhibited nerve-induced contractions of the bladder, providing evidence that CB2 receptors are important in micturition. **Taken together, these studies suggest that CB receptors in the bladder may have a modulatory role in sensory afferent signaling,** a greater understanding of which could lead to new therapeutic strategies for treatment of bladder disorders.

Opioid Peptides.

The risk of opioid-related bladder dysfunction (urinary retention) is an important issue and has been well studied in postoperative patients for analgesia. Opiates and their analogues (mainly because of µ-opioid receptor agonism) not only decrease bladder sensation but also can increase sphincter tone, resulting in increased outlet resistance (Durant and Yaksh, 1988). Both effects increase the risk of urinary retention. There are also reports in animals of increased bladder capacity and compliance after intravenous or intrathecal tramadol. Although no prospective studies have been done, the half-life of the opioid may also affect risk of retention: orthopedic patients receiving fentanyl (which exhibits a short half-life) reported less risk for retention compared with those receiving morphine (Gallo et al., 2008). Studies have also evaluated whether reducing the dose of opioid by combining with nonsteroidal anti-inflammatory drugs could lead to less retention. Most have concluded that although concurrent use of COX-2 inhibitors led to less opioid consumption and even decreased risk of associated nausea and constipation, the risk of acute urinary retention was not affected (Marret et al., 2005; Romsing et al., 2005).

Pelvic Organ Interactions: Crosstalk Between Bladder and Bowel.

Patients with irritable bowel syndrome (IBS) often report LUTS, including nocturia, frequent and urgent micturition, and incomplete emptying (Whorwell et al., 1986). The counterpart is also true with patients with BPS/IC who have bowel symptoms (Alagiri et al., 1997). These observations are consistent with the concept of **cross-organ sensitization,** which extends to different abdominal and pelvic structures and contributes to a more generalized chronic pelvic pain syndrome (Brumovsky and Gebhart, 2010). In experimental models, colonic inflammation has been shown to lead to increased frequency of bladder contractions and altered micturition reflexes (Pezzone et al., 2005). Similarly, experimental bladder inflammation has been reported to sensitize the bowel to distention (Bielefeldt et al., 2006). Such cross-organ sensitization has also been demonstrated among the uterus, pelvic urethra, and vagina. In men there is the potential for cross-organ sensitization between the prostate and other pelvic organs.

The mechanisms underlying cross-organ sensitization have not been fully elucidated, but there are potentially several levels at which the sensory innervation to the different pelvic structures can interact. In terms of peripheral mechanisms there is evidence that afferent fibers branch extensively to innervate multiple target structures. Axonal tracing studies using different retrograde tracers injected into the bladder and bowel reveal a number of DRG neurons carrying both labels, although the numbers are low. Similarly, dichotomizing afferents have been shown to innervate the colon and uterus with DRGs expressing TRPV1 and $P2X_3$ receptors, implying a role in nociception. Sensitization of the endings in one organ by local inflammation would likely affect overall sensitivity after upregulation in excitability in all terminal receptive fields. Central sensitization may also contribute to cross-organ sensitization. Excitability of spinal neurons receiving afferent input from the bladder has been shown to respond to afferent input from other pelvic structures such as the colon (Fig. 110.29; Clemens et al., 2008; Malykhina, 2007). Second-order neurons in the spinal cord therefore receive convergent input from various visceral structures as well as somatic inputs. The latter explains the phenomenon of referred pain, wherein sensations from the viscera are experienced in the associated somatic sensory field, the classic example being angina. Such viscerosomatic convergence has been extensively investigated, and viscerovisceral referral has received attention. Nevertheless, convergent inputs would explain the poor localization of pelvic pain and the difficulty in diagnosis and treatment.

FIG. 110.29 Schematic representation of convergent afferent pathways. *1,* Convergence of sensory neural pathways within a dorsal root ganglion *(red route).* The propagation of noxious stimulus from a diseased pelvic organ to a normal adjacent structure occurs via dichotomizing afferents as a result of an "axon-reflex" mechanism. Axon-reflex–antidromic propagation of action potentials (APs) from dorsal root ganglion to the periphery. *2,* Convergence of afferent information in the spinal cord *(blue route).* DRR refers to dorsal root reflexes (antidromic conductance via sensory fibers from the spinal cord to the periphery). Note that an output neuron belongs to the population of intermediolateral neurons (not motoneurons) localized mostly in laminae VI to VII. *3,* Convergence of afferent inputs from two different pelvic organs in the brain *(green route).* Convergent neurons within the dorsal root ganglion, in the spinal cord, and in the brain are shown by *star* symbol. Orthodromic propagation of APs from pelvic organs to the points of convergence is depicted by *solid lines* and *arrows* in respective color for each route. Anterograde AP propagation

from the brain, the spinal cord, and the dorsal root ganglion to the periphery is shown by *dotted lines.* (From Malykhina AP: Neural mechanisms of pelvic organ cross-sensitization. *Neuroscience* 149:660–672, 2007.)

Key Points: Afferent Pathways

- Studies of the properties of bladder afferents in the pelvic nerve, particularly in the rat, indicate that in-series tension receptors, volume receptors, and silent afferents (including nociceptors) are present.
- Intravesical irritant chemicals reduce the pressure thresholds of most of these endings, including the high-threshold receptors.
- A substantial proportion of the C-fiber afferent population is silent (i.e., insensitive to normal distention). However, these fibers become mechanosensitive after the action of various chemical mediators.
- During inflammation and possibly other pathologic conditions, there is recruitment of mechanosensitive C fibers that form a new functional afferent pathway. This is the rationale for intravesical C-fiber neurotoxin capsaicin and RTX therapy (Chancellor and de Groat, 1999).

Efferent Pathways to the Bladder

Three main neural pathways regulate LUT efferent activity: (1) **sacral parasympathetic** (pelvic) nerves provide excitatory input to the bladder; (2) **thoracolumbar sympathetic** (hypogastric) nerves provide inhibitory input to the bladder and excitatory input to the bladder neck and urethra; and (3) **sacral somatic** (pudendal) nerves innervate the striated muscles of the sphincters and pelvic floor (Fig. 110.30; Kluck, 1980). Parasympathetic postganglionic fibers terminate predominantly at the detrusor muscle and release ACh, resulting in detrusor contraction during voiding. Studies in animals have shown that sympathetic postganglionic fibers release noradrenaline (NA) and contribute to bladder relaxation during storage (via stimulation of β-adrenergic receptors expressed in detrusor).

FIG. 110.30 Mechanism of storage and voiding reflexes. (A) Storage reflexes. During the storage of urine, distention of the bladder produces low-level bladder afferent firing. Afferent firing, in turn, stimulates the sympathetic outflow to the bladder outlet (base and urethra) and pudendal outflow to the external urethral sphincter. These responses occur by spinal reflex pathways and represent "guarding reflexes," which promote continence. Sympathetic firing also inhibits detrusor muscle and transmission in bladder ganglia. (B) Voiding reflexes. At the initiation of micturition, intense vesical afferent activity activates the brainstem micturition center, which inhibits the spinal guarding reflexes (sympathetic and pudendal outflow to the urethra). The pontine micturition center also stimulates the parasympathetic outflow to the bladder and internal sphincter smooth muscle. Maintenance of the voiding reflex is through ascending afferent input from the spinal cord, which may pass through the periaqueductal gray matter (PAG) before reaching the pontine micturition center.

Terminal Nerve Fibers.

Smooth muscle cells in the bladder are grouped into fascicles, several of which make up a muscle bundle. They receive a dense innervation, which runs in line with the axis of the fascicle and is derived from coarse nerve trunks in the connective tissue around the fascicles and bundles. This innervation mediates the widespread coordinated detrusor contraction accompanying voiding. The nerve supply is illustrated in Fig. 110.6 (Maas et al., 2005), and the anatomic relationship between the preterminal innervation and the muscle fascicles has been described in a serial sectioning study in the human bladder (Kluck, 1980).

The majority of nerves innervating the detrusor express acetylcholinesterase and vesicular acetylcholine transferase (VAChT) (Dixon et al., 1983; Ek et al., 1977; Maas et al., 2005) and are thought to be parasympathetic. EFS studies have been used to elucidate the neurotransmitter content from muscle strips (with or without the mucosa). ACh and ATP appear to provide the majority of the excitatory input, because EFS responses are blocked by muscarinic receptor antagonists combined with purinergic antagonists. Both transmitters are released in the innervated muscle layer and persist after mucosal removal. Apart from ACh and ATP, there are additional substances present in parasympathetic efferents (vasoactive intestinal polypeptide [VIP], NOS, galanin), which allow immunohistochemical subclassification of nerve fibers and raise the question as to whether additional transmitters (other than ACh and ATP) have a role in normal micturition function or disease pathophysiology. In addition, cholinergic nerves are also present in the suburothelium, where most also contain neuropeptide Y (NPY) and tyrosine hydroxylase, and some also contain NOS. In the muscle of the trigone, the most common axons contain VIP and NPY, with noradrenergic axons forming only a sparse supply. Indeed, noradrenergic neurons are rare in the detrusor and absent in the urothelium (Wanigasekara et al., 2003).

Parathyroid hormone-related protein (PTHrP) released from detrusor smooth muscle (DSM) upon stretch may act as an endogenous DSM relaxant during bladder filling (Steers et al., 1998). A study in the rat bladder demonstrated that PTHrP potently suppressed spontaneous phasic contractions, while exerting only a modest inhibitory effect on carbachol-induced contractions (Nishikawa et al., 2013). PTH1R, a PTHrP receptor, predominantly locates in the muscular layers of the bladder wall (Lee et al., 2016; Nishikawa et al., 2015), and the concurrent expression of PTHrP in DSM indicated that PTHrP may function as a relaxing factor in an autocrine or paracrine fashion. Bath-applied PTHrP largely suppresses spontaneous contractions, whereas little affects cholinergic-induced contractions, indicating that PTHrP appears important for normal bladder function as well as a therapeutic target for overactive bladder. Endogenous and exogenously administrated PTHrP may not disturb neutrally mediated detrusor contractions during the voiding phase, while effectively suppressing spontaneous contractions that could stimulate afferent nerve firing. In contrast, downregulation of PTHrP mediated stabilization of DSM contractility may result in overactive bladder or reduced bladder capacity. Indeed, specimens taken from patients who have undergone bladder augmentation invariably show negative PTH1R staining in their DSM (Nishikawa et al., 2015). Because the detrusor has a 10-fold higher sensitivity to PTHrP compared with the muscularis mucosae and they are separated by layers of connective tissue, PTHrP may function as autocrine relaxant of DSM without suppressing mucosa contractility (Lee et al., 2016). In other smooth muscles, PTHrP acts via the adenylyl cyclase-cyclic AMP-PKA pathway. However, the involvement of this pathway in detrusor relaxation has not been established. Further studies are needed to explore the mechanism of PTHrP-induced suppression of spontaneous DSM contractions.

Spinal Ascending and Descending Influences: Transmitters

Glutamate.

Glutamate is present in the terminals of primary afferent neurons in the spinal cord along with interneurons and fibers originating in the medulla oblongata. In general, **glutamatergic neurons tend to be excitatory**, contrasting with generally inhibitory effects of glycinergic neurons; however, excitatory and inhibitory effects of transmitters can be reversed by the nature of the postsynaptic neuron. Thus glutamatergic neurons can indirectly have an inhibitory effect if an inhibitory neuron is interposed before the ultimate target (de Groat and Yoshimura, 2001). Glutamate acts on spinal neurons through a variety of receptor subtypes including *N*-methyl-D-aspartate (NMDA) receptors, which are important in controlling polysynaptic reflex pathways at the lumbosacral levels (Fig. 110.31). With aging, there is a decrease in the density of glutamatergic synaptic inputs, which may influence urinary tract function (Ranson et al., 2007).

FIG. 110.31 Diagram of the central reflex pathways that regulate micturition in the cat. Normally, micturition is initiated by a supraspinal reflex pathway passing through the pontine micturition center (PMC) in the brainstem. The pathway is triggered by myelinated afferents (Aδ) connected to tension receptors in the bladder wall (detrusor). Spinal tract neurons carry information to the brain. During micturition, pathways from the PMC activate the parasympathetic outflow to the bladder and inhibit the somatic outflow to the urethral sphincter. Transmission in the PMC is modulated by cortical-diencephalic mechanisms. Interruption of these mechanisms leads to bladder instability. In spinal cord–transected animals, connections between the brainstem and the sacral spinal cord are interrupted and micturition is initially blocked. In animals with chronic spinal cord injury, a spinal micturition reflex emerges that is triggered by unmyelinated (C-fiber) bladder afferents. The C-fiber reflex pathway is usually weak or undetectable in animals with an intact nervous system. Stimulation of the C-fiber bladder afferents by instillation of ice water into the bladder (cold stimulation) activates voiding reflexes in patients with spinal cord injury. Capsaicin (20 to 30 mg/kg subcutaneously) blocks the C-fiber reflexes in cats with chronic spinal cord injury but does not block micturition reflexes in intact cats. Intravesical capsaicin also suppresses bladder instability and cold-evoked reflexes in patients with neurogenic bladder dysfunction. Glutamic acid is the principal excitatory transmitter in the ascending and descending limbs of the micturition reflex pathway, as well as in the reflex pathway controlling sphincter function. Glutamate acts on *N*-methyl-D-aspartate (NMDA) and α-amino-3-hydroxy-5-methylisoxazole-4-propionic acid (AMPA) glutamatergic receptors. Other neurotransmitters that regulate transmission in the micturition reflex

pathway include γ-aminobutyric acid (GABA), enkephalins (Enk), acetylcholine (ACh), and dopamine (DA). ACh and dopamine have excitatory and inhibitory effects on the pathway: excitatory (+) and inhibitory (−) synapse.

Glycine and γ-Aminobutyric Acid.

Glycinergic and GABAergic interneurons have a major role in neural control processes mediating bladder function (Shefchyk, 2002). **Glycinergic and GABAergic projections to the lumbosacral cord inhibit the micturition reflex and also inhibit glutamatergic neurons** (Miyazato et al., 2013). Clinically, DO can be inhibited by GABA receptor activation (Miyazato et al., 2008b, 2008c). Rectal distention prolongs the interval, decreases the amplitude, and shortens the duration of bladder contractions in rats; this effect is not seen after simultaneous intrathecal injection of low-dose strychnine (a selective glycine-receptor antagonist) and bicuculline (GABA-A receptor antagonist), suggesting that the inhibitory rectovesical reflex involves glycinergic and GABAergic mechanisms in the lumbosacral spinal cord, which may be synergistic (Miyazato et al., 2004).

Serotonin.

Spinal reflex circuits involved in voiding function have a dense serotonergic (5-hydroxytryptamine [5-HT]) innervation (de Groat, 2002). Immunocytochemical studies in rats, cats, and primates show that lumbosacral sympathetic and parasympathetic autonomic nuclei receive serotonergic inputs from the raphe nuclei (Kojima et al., 1983; Mizukawa, 1980; Rajaofetra et al., 1992; Skagerberg and Bjorklund, 1985). **Activation of the central serotonergic system can suppress voiding by inhibiting the parasympathetic excitatory input to the urinary bladder,** and 5-HT elicits a prolonged activation of thoracic sympathetic preganglionic neurons. Stimulation of the raphe nuclei in the cat inhibits reflex bladder activity (Chen et al., 1993; McMahon and Spillane, 1982; Sugaya et al., 1998). 5-HT$_{1A}$ and 5-HT$_2$ receptors are present in the sacral parasympathetic nucleus. However, in different species, serotonin (5-HT) may have varying functions in the central nervous control of bladder activity. For example, activation of 5-HT$_{1A}$ receptors facilitates reflex bladder activity in rats (de Groat, 2002; Lecci et al., 1992) and has been used to reverse the effects of diabetes mellitus (Gu et al., 2012).

Duloxetine, a combined norepinephrine and 5-HT reuptake inhibitor

(Sharma et al., 2000), **has been shown, in a bladder-irritated model, to increase the neural activity of the urethral sphincter and the bladder** (Cannon et al., 2003; Thor and Donatucci, 2004; Thor and Katofiasc, 1995). Duloxetine appears to have effects on the bladder and the sphincter and has been proposed for treatment of stress incontinence and urgency incontinence (Cannon et al., 2003; Thor and Donatucci, 2004). Duloxetine increases the neural activity to the EUS and decreases bladder activity through effects on the CNS in cats (Thor and Donatucci, 2004). In a rat study, duloxetine also enhances the urethral continence reflex during sneezing as evidenced by an increase in sneeze-induced pressure responses at the middle urethra, although the effect appears to be mainly mediated by α_1-adrenoceptors (Miyazato et al., 2008a).

Adrenergic Transmitters.

Descending catecholaminergic neurons are primarily located in the upper medulla or pons (Ranson et al., 2003). In clinical use, nonselective α_1-adrenergic antagonists influence urine flow and LUTS; the two effects probably occur by different mechanisms, and central or peripheral locations may be responsible (Somogyi et al., 1995). Reflex bladder activity is modulated by at least two spinal α_1-adrenergic mechanisms. First, there is inhibitory control of reflex bladder contractions, probably by modulation of afferent processing. Second, there is excitatory modulation of the amplitude of bladder contractions as a result of regulation of the descending glutamatergic limb of the spinobulbospinal bladder reflex pathway (de Groat et al., 1999; Yoshiyama et al., 2000). α_{1A}-Adrenoceptors constitute 70% and α_{1B}-adrenoceptors constitute 30% of the α-adrenergic receptors in the rat lumbar spinal cord (Wada et al., 1996), whereas α_{1D}-adrenoceptors do not appear to have a significant role.

Blood pressure, vascular resistance, and tissue blood flow are also regulated by α-adrenergic receptors. Aging is thought to affect pelvic blood flow and thus bladder function. Pharmacologic blockade of the vascular α_{1B} adrenoceptor may increase pelvic blood flow and contribute to an improvement in bladder dysfunctions associated with aging and/or hypertension (Yono et al., 2011). β_3-Adrenoceptors, although well documented peripherally, are also present at a number of sites peripherally as well as in the rat sacral spinal cord. A number of studies have demonstrated that these agonists (via effects on bladder afferents and detrusor smooth muscle) may be a promising treatment for OAB (Chapple et al., 2014).

Purinergic Transmitters.

ATP acting via purinergic receptors modulates bladder function mediated by afferent and efferent pathways involved in urine storage and emptying. ATP is released together with NA and NPY from sympathetic nerves. It is also released as a cotransmitter with ACh from parasympathetic nerves supplying the bladder. Cotransmission likely offers subtle, local variations in neurotransmission and neuromodulation mechanisms (Burnstock, 2009). Purinergic contribution to parasympathetic stimulation has been shown to exist in a variety of species including rat, rabbit, and guinea pig (Burnstock, 1996; Burnstock et al., 1972; Chancellor et al., 1992). In contrast, there is less evidence that purinergic neurotransmission exists in humans, at least regarding normal responses to stimulation, but it may play a role in pathological conditions such as DO or BOO (Burnstock, 2001b; O'Reilly et al., 2001a; Palea et al., 1993).

ATP acts on two families of purinergic receptors: an ion channel family (P2X) and a G protein–coupled receptor family (P2Y) (Inoue and Brading, 1990; Inoue and Gabella, 1991; McMurray et al., 1998). Seven P2X subtypes and eight P2Y subtypes have been identified. Analysis of the structure-activity relationships of a series of excitatory purinergic agonists on the guinea pig bladder revealed an order of potency consistent with $P2X_1$ or $P2X_2$ receptors (Burnstock, 2001a; Zhong et al., 2001). In other species various studies suggested that multiple purinergic excitatory receptors are present in the bladder (Burnstock, 2001b).

Immunohistochemical experiments with specific antibodies for different P2X receptors showed that $P2X_1$ receptors are the dominant subtype in membranes of rat detrusor muscle and vascular smooth muscle in the bladder (Lee et al., 2000). The predominant expression of $P2X_1$ receptors has also been confirmed in the human bladder (O'Reilly et al., 2001a, 2001b). Investigators also found that the amount of $P2X_1$ receptors was increased in the obstructed bladder compared with the control bladder, suggesting upregulated purinergic mechanisms mediating OAB resulting from BOO (O'Reilly et al., 2001a).

Key Points: Spinal Circuitry Neurotransmitters

- Glutamate plays an important role in the spinal efferent circuitry supporting micturition.
- The spinal noradrenergic system, mediated by α_1-adrenoceptors, has a

modulatory role in controlling micturition by inhibiting afferent inputs from the bladder and facilitating the descending limb of the spinal micturition reflex to increase bladder contractility.

- Transmitters such as 5-HT, purines, glycine, and GABA appear to selectively modulate the volume threshold by actions in the sacral spinal cord. The role of other potential excitatory transmitters remains to be examined.
- These mechanisms seem to be favorable for development of novel drug therapies.
- Glutamate appears to be involved as an excitatory transmitter in the supraspinal circuitry controlling micturition.
- Glutamate may also be a mediator of DO after neural injury.
- Several substances can exert significant modulatory influences on the supraspinal circuits (see Fig. 110.31) and can have dramatic influences on micturition.
- The receptors for these substances represent potential sites for therapeutic intervention.

Reflex Circuitry Controlling Continence and Micturition.

Multiple reflex pathways organized in the brain and spinal cord mediate coordination between the urinary bladder and the urethra. The central pathways controlling LUT function are organized as simple on-off switching circuits (Fig. 110.32) that maintain a reciprocal relationship between the urinary bladder and the urethral outlet (De Groat, 1975; de Groat and Booth, 1993; de Groat et al., 1993). Some reflexes promote urine storage, whereas others facilitate voiding (see Fig. 110.30). It is also possible that individual reflexes may be linked together in a serial manner to create complex feedback mechanisms. For example, **the bladder-to-EUS guarding reflex that triggers sphincter contractions during bladder filling could, in turn, activate sphincter muscle afferents that initiate an inhibition of the parasympathetic excitatory pathway to the bladder. Thus a bladder-to-sphincter-to-bladder reflex pathway could, in theory, contribute to the suppression of bladder activity during urine storage. Alterations in these primitive reflex mechanisms may contribute to neurogenic bladder dysfunction.** Direct activation of these reflexes by electric stimulation of the sacral spinal roots very likely contributes to therapeutic effects of sacral nerve root neuromodulation (Chancellor and

Chartier-Kastler, 2000; Dijkema et al., 1993).

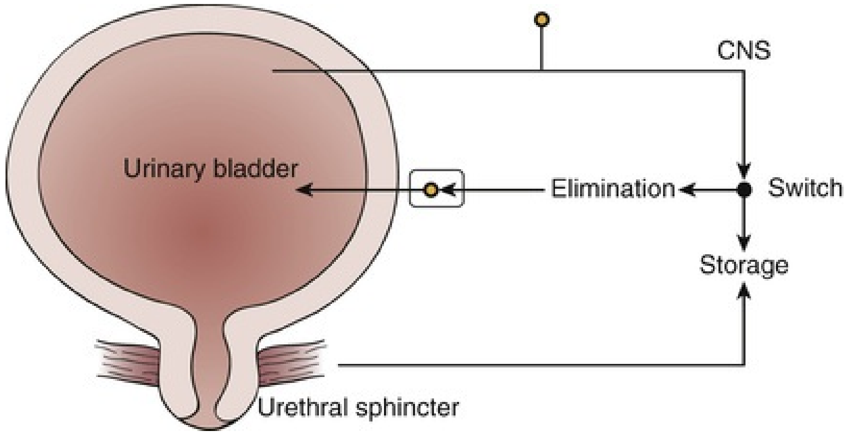

FIG. 110.32 Diagram illustrating the anatomy of the lower urinary tract and the "switchlike" function of the micturition reflex pathway. During urine storage, a low level of afferent activity activates efferent input to the urethral sphincter. A high level of afferent activity induced by bladder distention activates the switching circuit in the central nervous system (CNS), producing firing in the efferent pathways to the bladder, inhibition of the efferent outflow to the sphincter, and urine elimination.

Storage Phase of the Bladder.

Intravesical pressure measurements during bladder filling in humans and animals reveal low and relatively constant bladder pressures when bladder volume is below the threshold for inducing voiding (Fig. 110.33). **The accommodation of the bladder to increasing volumes of urine is dependent on the intrinsic properties of the vesical smooth muscle and stroma, as well as the quiescence of the parasympathetic efferent pathway** (de Groat and Booth, 1993; de Groat et al., 1993; Torrens and Morrison, 1987; Yoshimura et al., 2008). In addition, the urothelium also plays an important role in accommodating urine storage via changes in the apical (umbrella) cell membrane and release of a number of neuromediators that can influence bladder smooth muscle tone (Wang et al., 2005). **The bladder sympathetic reflex also contributes as a negative feedback or urine storage mechanism that promotes closure of the urethral outlet and inhibits neurally mediated contractions of the bladder during bladder filling** (de Groat and Theobald, 1976; Table 110.3). Reflex activation of the sympathetic outflow to the LUT can be triggered by afferent activity induced by distention of the urinary bladder (de

Groat and Booth, 1993; de Groat and Theobald, 1976; de Groat et al., 1993). This reflex response is organized in the lumbosacral spinal cord and persists after transection of the spinal cord at the thoracic levels (Fig. 110.34). **However, this bladder sympathetic mechanism to suppress bladder contractions during urine storage may be weak in humans,** given that bilateral retroperitoneal lymph node dissection, in which the sympathetic chains are destroyed, results in no discernible alteration of filling or storage function in humans.

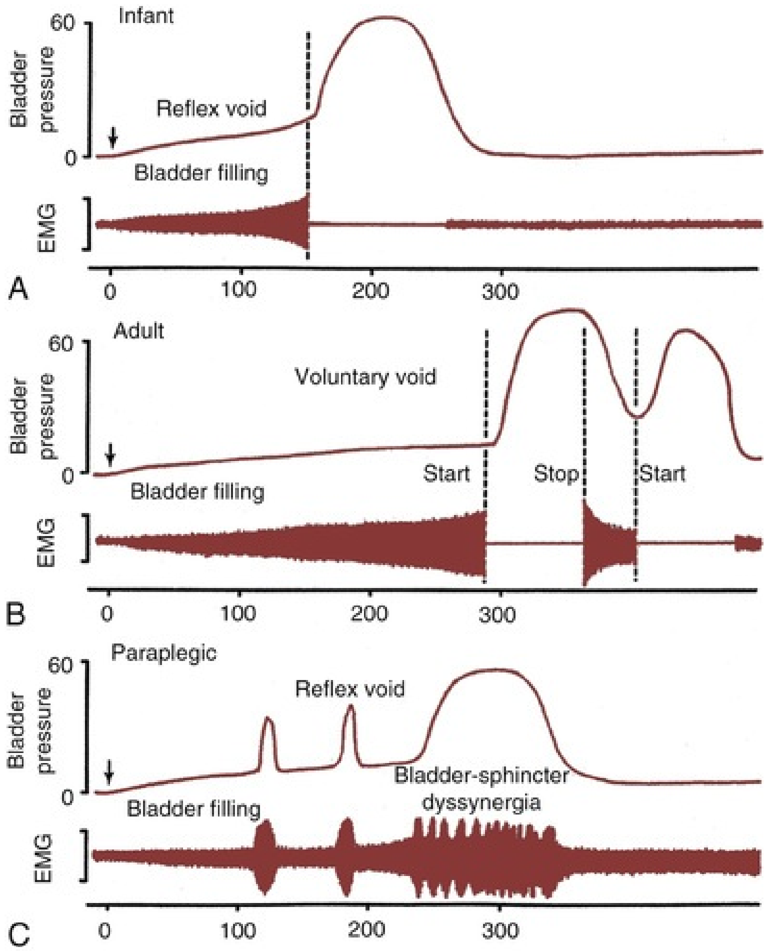

FIG. 110.33 Combined cystometrogram and sphincter electromyogram (EMG) comparing reflex voiding responses in an infant (A) and in a paraplegic patient (C) with a voluntary voiding response in an adult (B). The x-axis in all records represents bladder volume in milliliters, and the y-axis represents bladder pressure in centimeters of water and electrical activity of the electromyographic recording. On the left side of each trace, the *arrows* indicate the start of a slow infusion of fluid into the bladder (bladder filling). Vertical *dashed lines* indicate the start of sphincter relaxation that precedes by a few seconds the bladder contraction in A and

B. In B, note that a voluntary cessation of voiding (stop) is associated with an initial increase in sphincter electromyographic activity followed by a reciprocal relaxation of the bladder. A resumption of voiding is again associated with sphincter relaxation and a delayed increase in bladder pressure. On the other hand, in the paraplegic patient (C), the reciprocal relationship between bladder and sphincter is abolished. During bladder filling, transient uninhibited bladder contractions occur in association with sphincter activity. Further filling leads to more prolonged and simultaneous contractions of the bladder and sphincter (bladder-sphincter dyssynergia). Loss of the reciprocal relationship between bladder and sphincter in paraplegic patients interferes with bladder emptying. (From de Groat WC: Basic neurophysiology and neuropharmacology. In Abrams P, Khoury S, Wein A, editors: *Incontinence,* Plymouth, UK, 1999, Health Publications, p 112.)

	Activation of parasympathetic outflow to the urethra	

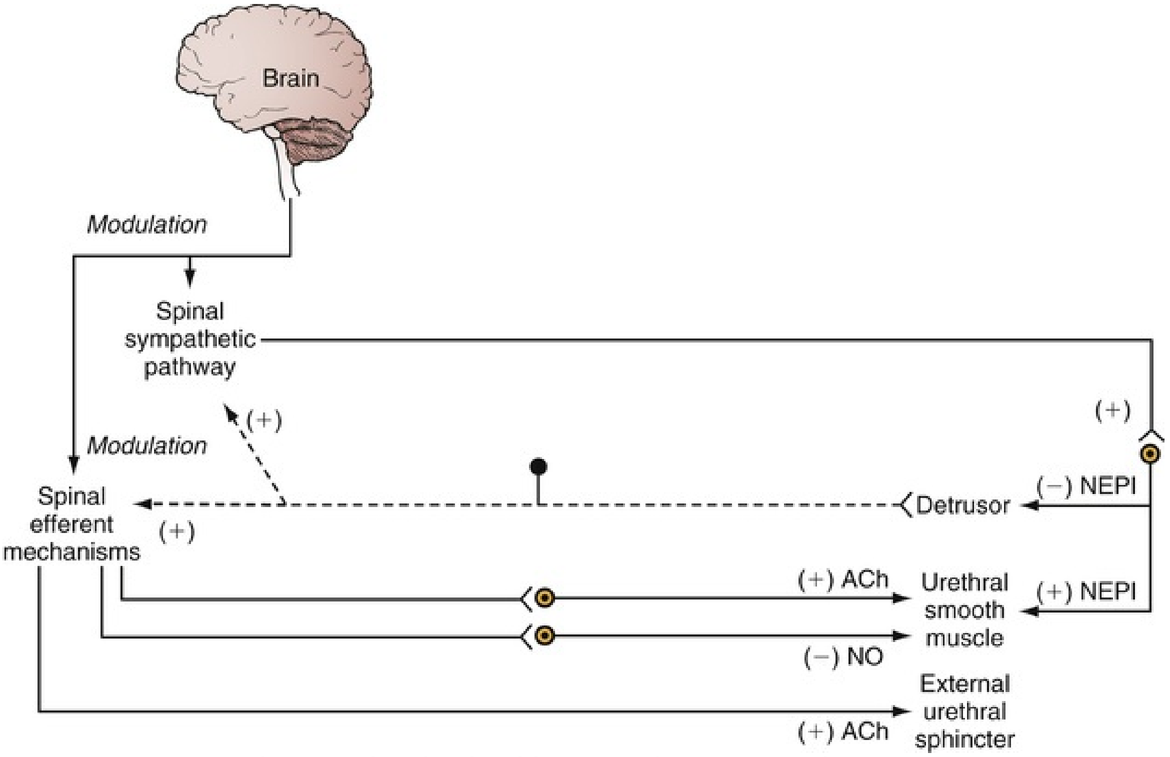

FIG. 110.34 Diagram showing bladder to urethra reflex pathways. Afferent pathway *(dashed line)* from the detrusor activates spinal reflex mechanisms that induce firing in somatic cholinergic nerves to the external urethral sphincter, sympathetic adrenergic nerves to the urethral smooth muscle, and cholinergic and nitrergic nerves to the urethral smooth muscle. Bulbospinal pathways from the brain can modulate these spinal reflex mechanisms. *ACh,* Acetylcholine; *NEPI,* norepinephrine; *NO,* nitric oxide; +, excitatory mechanism; −, inhibitory mechanism.

During bladder filling, the activity of the sphincter electromyogram also increases (see Fig. 110.33), reflecting an increase in efferent firing in the pudendal nerve and an increase in outlet resistance that contributes to the maintenance of urinary continence. Pudendal motoneurons are activated by bladder afferent input (the guarding reflex) (Park et al., 1997), whereas during micturition the motoneurons are reciprocally inhibited (de Groat and Booth, 1993; de Groat et al., 1993). EUS motoneurons are also activated by urethral or perineal afferents in the pudendal nerve (Fedirchuk and Hochman, 1992). This reflex may represent, in part, a continence mechanism that is activated by proprioceptive afferent input from the urethra or pelvic floor and that induces closure of the urethral outlet. These excitatory sphincter reflexes are organized in the spinal cord. Inhibition of EUS reflex activity during micturition is dependent, in part, on supraspinal mechanisms, because it is weak or absent in chronically spinalized animals and humans, resulting in simultaneous contractions of bladder and sphincter (i.e., detrusor-sphincter dyssynergia) (Blaivas, 1982; Rossier and Ott, 1976).

Sphincter to Bladder Reflexes.

It is well known that stimulation of somatic afferent pathways projecting in the pudendal nerve to the caudal lumbosacral spinal cord can inhibit voiding function. The inhibition can be induced by activation of afferent input from various sites, including the penis, vagina, rectum, perineum, urethral sphincter, and anal sphincter (de Groat and Booth, 1979, 1993; de Groat et al., 1979, 1993, 2001; de Groat and Yoshimura, 2001). Electrophysiologic studies in cats showed that the inhibition was mediated by suppression of interneuronal pathways in the sacral spinal cord and also by direct inhibitory input to the parasympathetic preganglionic neurons (De Groat et al., 1982).

On the basis of experiments in the laboratory and the review of medical literature, contractions of the EUS, and possibly other pelvic floor striated muscles, are likely to stimulate firing in muscle proprioceptive afferents, which then activate central inhibitory mechanisms to suppress the micturition reflex (see Fig. 110.33). A similar inhibitory mechanism has been identified in monkeys by directly stimulating the anal sphincter muscle (McGuire et al., 1983). In monkeys, at least part of the inhibitory mechanism must be localized in the spinal cord, because it persisted in T4 chronically paraplegic animals.

It is well known that stimulation of somatic afferent pathways projecting in the pudendal nerve to the caudal lumbosacral spinal cord can inhibit voiding function. The inhibition can be induced by activation of afferent input from various sites, including the penis, vagina, rectum, perineum, urethral sphincter, and anal sphincter (de Groat and Booth, 1979, 1993; de Groat and Yoshimura, 2001; de Groat et al., 1993, 2001). Electrophysiologic studies in cats showed that the inhibition was mediated by suppression of interneuronal pathways in the sacral spinal cord and also by direct inhibitory input to the parasympathetic preganglionic neurons (De Groat et al., 1982).

On the basis of laboratory experiments and review of the medical literatures, it is likely that contractions of the EUS, and possibly other pelvic floor striated muscles, stimulate firing in muscle proprioceptive afferents, which then activate central inhibitory mechanisms to suppress the micturition reflex (Fig. 110.35). A similar inhibitory mechanism has been identified in monkeys by directly stimulating the anal sphincter muscle (McGuire et al., 1983). In monkeys, at least part of the inhibitory mechanism must be localized in the spinal cord, because it persisted in T4 chronically paraplegic animals.

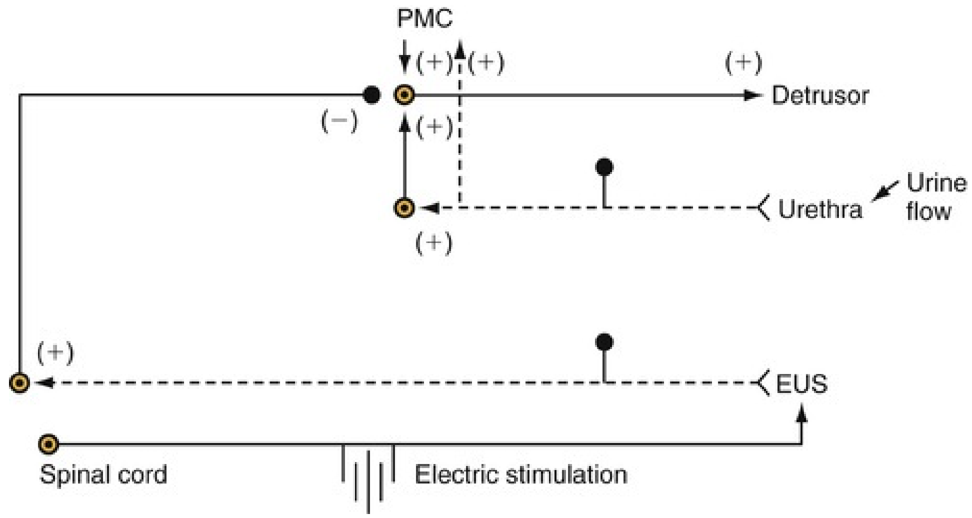

FIG. 110.35 Urethra to bladder reflexes. Activity in afferent nerves *(dashed lines)* from the urethra can facilitate parasympathetic efferent outflow to the detrusor by means of a supraspinal pathway passing through the pontine micturition center (PMC), as well as a spinal reflex pathway. Afferent input from the external urethral sphincter (EUS) can inhibit parasympathetic outflow to the detrusor through a spinal reflex circuit. Electric stimulation of motor axons in the S1 ventral root elicits an EUS contraction and EUS afferent firing that, in turn, inhibits reflex bladder activity. +, Excitatory mechanism; −, inhibitory mechanism.

Somatic to Visceral Reflexes.

There is evidence that stimulation of the sacral nerve roots using implanted electrodes (sacral neuromodulation) may be effective in patients with refractory OAB as well as in nonobstructive urinary retention, in patients refractory to conventional methods. Although the specific site of action is still unknown, various mechanisms have been described, including the modulation of CNS pathways (including somatic afferent inhibition of sensory processing) and the restoration of brainstem autoregulation (Leng and Chancellor, 2005; Thompson et al., 2010). Although more comprehensive evaluation is needed, another method that has been used as effective treatment for OAB and nonobstructive urinary retention is posterior tibial nerve stimulation (PTNS). Studies in anesthetized cats revealed that continuous tibial nerve stimulation (TNS) inhibited bladder activity that persisted after termination of the stimulus (Tai et al., 2011a,b), suggesting a role for treatment in bladder overactivity. In addition, this group also found evidence that an interaction between opioid and metabotropic glutamate receptor mechanisms may play a role in mechanisms underlying TNS-induced inhibition of bladder overactivity (Matsuta et al., 2013).

Emptying Phase of the Bladder.

The storage phase of the bladder can be switched to the voiding phase either involuntarily (reflexively) or voluntarily. The former is readily demonstrated in the human infant or in patients with neuropathic bladder when the bladder wall tension caused by increased volume of urine exceeds the micturition threshold. At this point, increased afferent firing from tension receptors in the bladder reverses the pattern of efferent outflow, producing firing in the sacral parasympathetic pathways and inhibition of sympathetic and somatic pathways. The expulsion phase consists of an initial relaxation of the urethral sphincter (see Fig. 110.33) followed in a few seconds by a contraction of the bladder, an increase in bladder pressure, and the flow of urine. Relaxation of the urethral smooth muscle during micturition is mediated by activation of a parasympathetic pathway to the urethra that triggers the release of NO, an inhibitory transmitter (Andersson, 1993), and by removal of excitatory inputs to the urethra. Secondary reflexes elicited by flow of urine through the urethra facilitate bladder emptying (de Groat and Booth, 1993; de Groat et al., 1993; Jung et al., 1999; Torrens and Morrison, 1987). These reflexes require the integrative action of neuronal populations at various levels of the neuraxis. The parasympathetic outflow to the detrusor and urethra has a more complicated central organization involving spinal and spinobulbospinal pathways passing through a micturition center in the pons (pontine micturition center [PMC]).

Urethra to Bladder Reflexes.

A landmark in the historical progress of neurobiology is the contribution of Barrington. Using his keen observational skills, Barrington (1931, 1941) reported that urine flow or mechanical stimulation of the urethra with a catheter could excite afferent nerves that, in turn, facilitated reflexive bladder contractions in the anesthetized cat (see Fig. 110.35). **He proposed that this facilitatory urethra-to-bladder reflex could promote complete bladder emptying.** Barrington identified two components of this reflex. One component was activated by a somatic afferent pathway in the pudendal nerve and produced facilitation by a supraspinal mechanism involving the PMC (see Fig. 110.35;

Barrington, 1931). Studies have confirmed the existence of this type of reflex by the pudendal nerve because low-frequency electric stimulation of afferent axons in the pudendal nerve in humans, or the deep perineal nerve (a caudal branch of the pudendal nerve) in cats, can initiate reflexive bladder contractions and voiding (Boggs et al., 2005; Shefchyk and Buss, 1998). The other component was activated by a visceral afferent pathway in the pelvic nerve and produced facilitation by a spinal reflex mechanism (Barrington, 1941).

Studies in the anesthetized rat have also provided additional support for Barrington's findings (Dokita et al., 1991). Measurements of reflexive bladder contractions, under isovolumetric conditions during continuous urethral perfusion (0.075 mL/min), revealed that the frequency of micturition reflexes was significantly reduced when urethral perfusion was stopped or after infusion of lidocaine (1%) into the urethra. Intraurethral infusion of NO donors (*S*-nitroso-*N*-acetylpenicillamine [SNAP] or nitroprusside, 1 to 2 mM) markedly decreased urethral perfusion pressure (approximately 30%) and decreased the frequency of reflex bladder contractions (45% to 75%) but did not change the amplitude of bladder contractions (Fig. 110.36). Desensitization of the urethral afferent with intraurethral capsaicin also dramatically altered the micturition reflex (Fig. 110.37). It was concluded that activation of urethral afferents during urethral perfusion could modulate the micturition reflex in the rat.

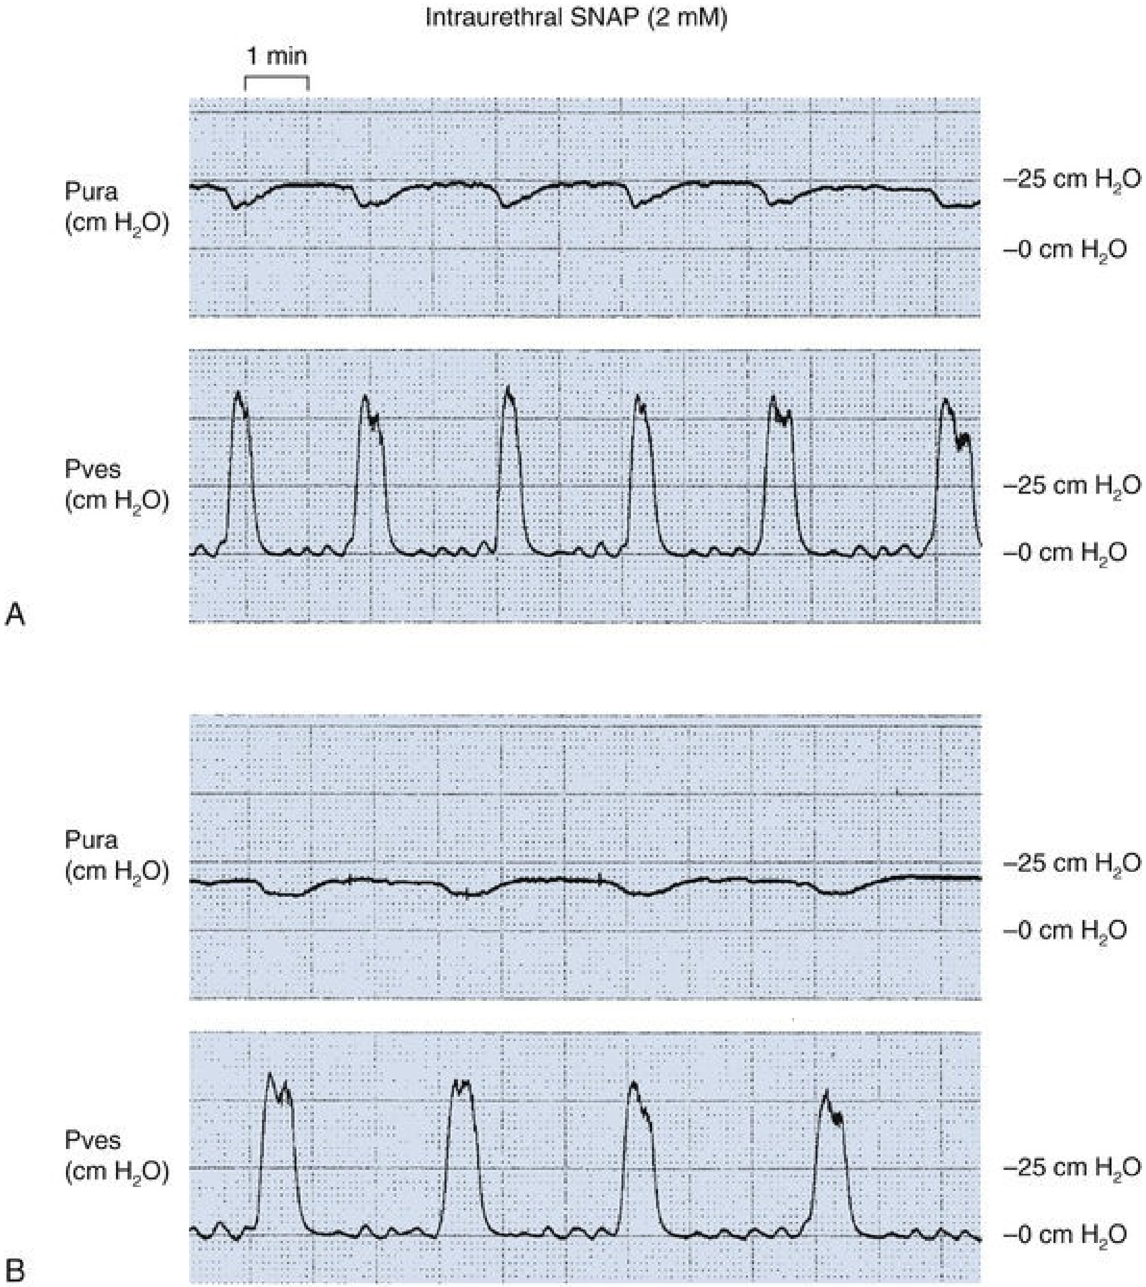

FIG. 110.36 Effects of intraurethral *S*-nitroso-*N*-acetylpenicillamine (SNAP) on the bladder pressure (Pves) and urethral pressure (Pura) in normal female rats. (A) Before treatment. (B) After intraurethral administration of SNAP (2 mM). Urethral perfusion pressure immediately decreased. In addition, bladder contraction frequency was significantly decreased. The duration of reflexive urethral relaxation was increased. (From Jung SY, Fraser MO, Ozawa H, et al.: Urethral afferent nerve activity affects the micturition reflex: implication for the relationship between stress incontinence and detrusor instability. *J Urol* 162:204–212, 1999.)

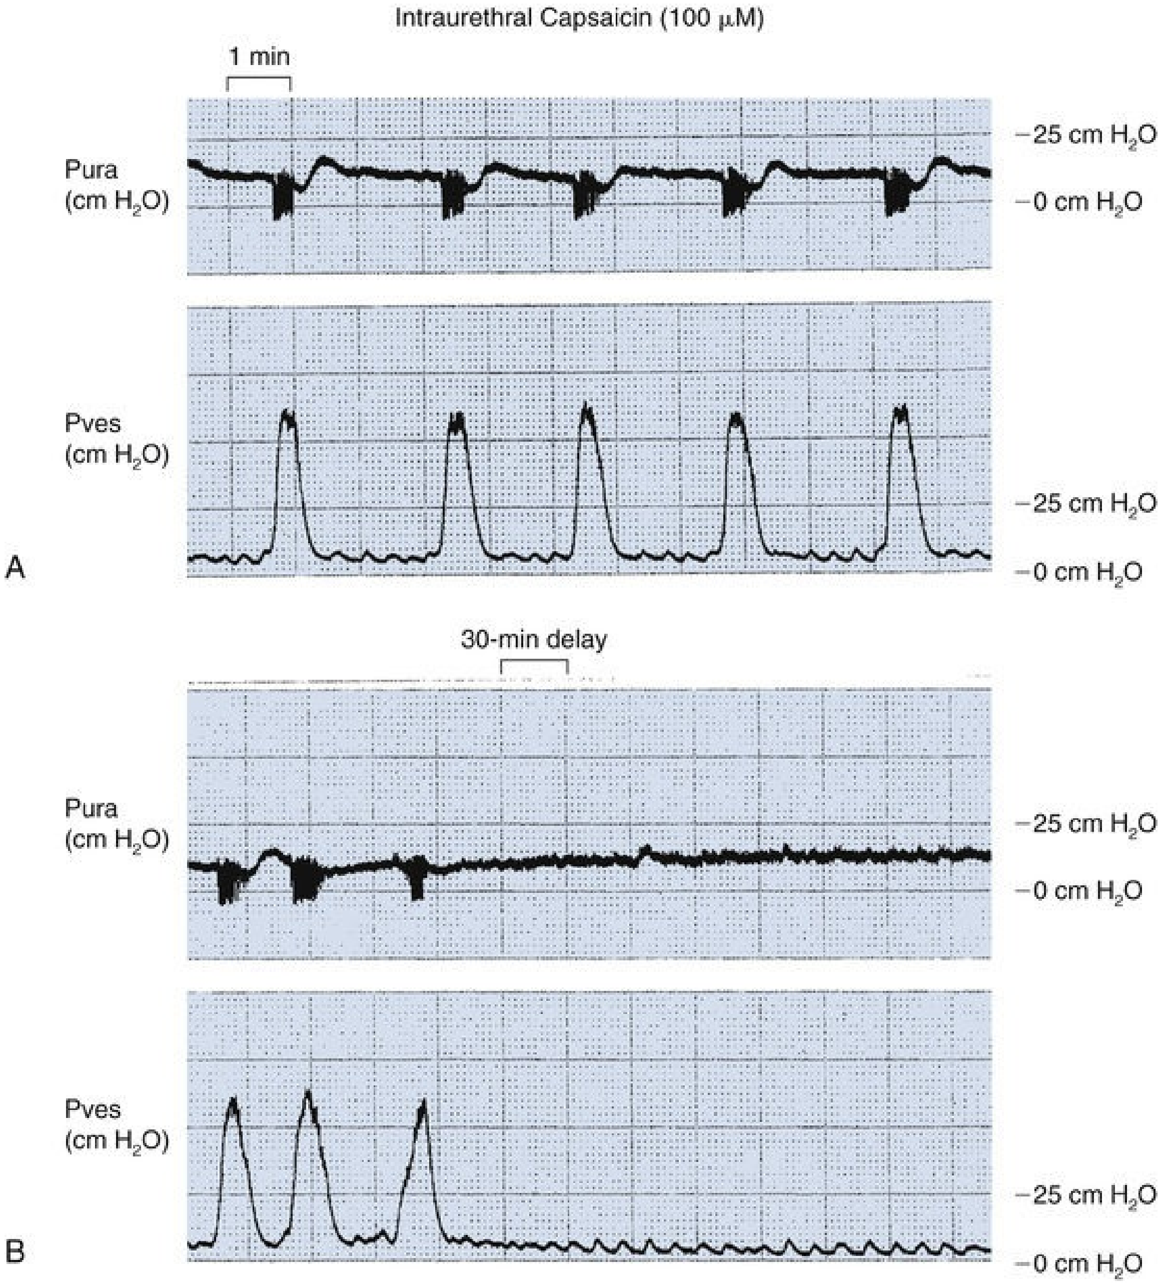

FIG. 110.37 Effects of intraurethral capsaicin on the bladder pressure (Pves) and urethral pressure (Pura) in normal female rats. (A) Before treatment. (B) After intraurethral administration of capsaicin (100 µM). Initially, intraurethral capsaicin instillation increased the bladder contraction frequency, but 30 minutes after continuous infusion, the activity was blocked. (From Jung SY, Fraser MO, Ozawa H, et al.: Urethral afferent nerve activity affects the micturition reflex: implication for the relationship between stress incontinence and detrusor instability. *J Urol* 162:204–212, 1999.)

Supraspinal Pathways

Pontine Micturition Center and Brainstem Modulatory Mechanisms.

The integral role of the brainstem in bladder function was initially realized by the demonstration in cats that micturition was abolished by lesions at the level of the inferior colliculus, whereas lesions anterior to the colliculus facilitated micturition, presumably by removing inhibitory influences (Barrington, 1921, 1925). Anatomic and physiologic studies in the rat and the cat have delineated midbrain–pontine–spinal cord circuits in reflexes controlling filling, storing, and emptying of the bladder (Fig. 110.38). The roles of pontine nuclei revealed by animal models translate well to humans as indicated by brain imaging during micturition (Blok and Holstege, 1997; Blok et al., 1997; Fukuyama et al., 1996; Kershen et al., 2003) and clinical cases showing that specific pontine lesions can result in either bladder continence or incontinence problems (Charil et al., 2003; Fukuyama et al., 1996; Sakakibara et al., 1996).

FIG. 110.38 Schematic depicting information flow among the bladder, spinal cord, and brain. In the rat, spinal cord interneurons relay information about the bladder to the pontine micturition center (PMC), Barrington nucleus, and PAG. The PMC also gets input from the PAG, lateral hypothalamus, and medial preoptic nucleus. PMC neurons project to the locus ceruleus (LC) and preganglionic parasympathetic neurons of the lumbosacral spinal cord that innervate the detrusor. There are also projections to premotor neurons in the dorsal gray commissure that innervate Onuf nucleus, which projects to the urethral sphincter. A pontine continence center (PCC) has been proposed in the cat and is localized to the L-region of the pons. Neurons here project to the Onuf nucleus.

The dorsal pontine tegmentum has been firmly established as an essential control center for micturition in normal subjects. First described by Barrington (1921), it has subsequently been called the *Barrington nucleus*, the *pontine micturition center* (Blok and Holstege, 1997), or the *M region* (Blok and Holstege, 1996; Holstege et al., 1996) because of its medial location. In 1925

Barrington was the first to describe a pontine control center for micturition in the cat after lesion studies (Barrington, 1921, 1925). This region was better localized to a nucleus in the dorsal pons (now termed the *Barrington nucleus)* using more discrete lesions that abolished micturition and caused urinary retention in cats and rats (Satoh et al., 1978; Tang, 1955). Lesions in humans as a result of stroke or multiple sclerosis in an analogous region similarly result in urinary retention (Komiyama et al., 1998).

Physiologic studies have confirmed the role of the Barrington nucleus in micturition. Electrical and chemical activation of Barrington nucleus neurons in rats and cats initiates bladder contractions and relaxes the urethral sphincter (Holstege et al., 1986; Mallory et al., 1991; Pavcovich and Valentino, 1995; Tanaka et al., 2003). Precise mapping of sites at which chemical stimulation elicits bladder contractions demonstrates a well-defined area localized to the Barrington nucleus (Pavcovich and Valentino, 1995). Single-unit recordings in rat pons revealed three types of responses to bladder contraction: an excitation that occurred only before contraction, an excitation that occurred before and was maintained during contraction, and an inhibition during contraction (Tanaka et al., 2003). Neurons that were activated just before contraction and that maintained activation during contraction were found in Barrington nucleus, whereas the other two types of neurons were scattered throughout the pontine tegmentum.

Micturition also requires an inhibition of the urethral sphincter to be coordinated with detrusor contraction. The striated urethral sphincter (rhabdosphincter) is controlled by the interaction between upper moto neurons and the lower motoneurons of the Onuf nucleus. Barrington nucleus neurons do not project to Onuf nucleus. Rather, in the cat a diffuse region ventrolateral to Barrington nucleus, termed the *L-region*, is thought to provide pontine control of sphincter function through its projections to Onuf nucleus (Holstege et al., 1979). For coordination between the detrusor and sphincter, there should be some form of reciprocal communication between these regions. However, a lack of connections between Barrington nucleus and the L-region is the reason for argument against sphincter regulation by Barrington nucleus through this route (Blok and Holstege, 1999). Rather, it has been proposed that Barrington nucleus indirectly inhibits Onuf nucleus neurons though excitatory projections to GABA premotor interneurons in the dorsal gray commissure (Blok and Holstege, 1999). In addition, Barrington nucleus projections onto inhibitory interneurons located in the intermediolateral cell column at the sacral segmental level have been described and may provide an inhibitory influence over Onuf nucleus; glycine and GABA are thought to play a role here (Blok and Holstege, 1998; Sie et al., 2001). Together, the anatomic and physiologic findings just described point to Barrington nucleus as being the command center for initiating and orchestrating the act of bladder emptying.

Central Circuitry Regulating Bladder Function by Transneuronal Tracing.

Transneuronal retrograde tracing from end organs with pseudorabies virus (PRV) has been an invaluable tool in delineating the central circuitry that regulates visceral function (Loewy, 1998). The population of rat brain neurons labeled from PRV injections in either the bladder wall or urethra of the rat exhibits an overlap and similar time course of labeling, supporting a close coordination of detrusor and urethral muscle function by brain circuits as previously suggested (Marson, 1997; Nadelhaft and Vera, 1996; Nadelhaft et al., 1992; Vizzard et al., 1995). The first neurons to be labeled in brain from bladder or urethra and therefore the most direct links to the spinal efferents are the ventral medullary raphe, parapyramidal reticular formation, A5, and Barrington nucleus. The periaqueductal gray (PAG), hypothalamus, and medial preoptic nucleus, which are prominent afferents to Barrington nucleus, are labeled at a slightly later time when the locus ceruleus (LC), cortex, and red nucleus are also labeled. PRV labeling from other pelvic viscera, including the distal colon, yields a similar pattern and time course, suggesting a certain degree of central coordination of these functions (Marson and Carson 3rd, 1999; Rouzade-Dominguez et al., 2003).

The PRV studies provide information regarding some hierarchy of neurons that is anatomically linked to the bladder and/or urethra. However, the PRV technique does not imply precise information about connectivity or functionality. This must be delineated by additional tract tracing between putatively connected brain nuclei and physiologic studies. For example, studies in humans indicate that voluntary control of voiding is dependent on connections between the frontal cortex and the septal-preoptic region of the hypothalamus, as well as on connections between the paracentral lobule and the brainstem. Lesions to these areas of cortex appear to directly increase bladder activity by removing cortical inhibitory control (de Groat and Booth, 1993; de Groat et al., 1993). Of the brain regions that are initially labeled with PRV from the bladder or urethra, most anatomic, electrophysiologic, and imaging studies have implicated the

Barrington nucleus as pivotal in regulating bladder function in animals and humans.

Neurotransmitters and Modulators Within Brainstem Networks.

Knowledge of the neurochemical signals within the central circuits controlling micturition is important for understanding how these circuits function and how they can be manipulated for the treatment of bladder dysfunctions. These were reviewed in detail by Holstege (2005) and by Fowler et al. (2008). Much of the current knowledge is based on studies using cats; less is known regarding rats and primates. **Glutamate is thought to be the primary neurotransmitter within Barrington nucleus neurons that innervate the preganglionic parasympathetic neurons responsible for detrusor contraction.** NMDA and non-NMDA receptors have been implicated in this response (Matsumoto et al., 1995a, 1995b; Yoshiyama et al., 1995; Yoshiyama and de Groat, 2005).

Barrington nucleus neurons express corticotropin-releasing factor (CRF) mRNA and protein, and a dense CRF terminal field is present in the region of preganglionic parasympathetic neurons of the rat lumbosacral spinal cord (Imaki et al., 1992; Valentino et al., 2000). Findings suggest that CRF has an inhibitory influence in this same pathway (Pavcovich and Valentino, 1995). Thus discrete chemical activation of Barrington nucleus neurons elicits bladder contraction that is enhanced by blocking the CRF influence in the lumbosacral spinal cord with a CRF antagonist. Serotonin appears to affect nervous control of bladder function at multiple levels, including sensory processing of bladder wall afferents within the dorsal horn of the spinal cord and at the level of the spinal motoneurons. In all cases this appeared to be an inhibitory influence on detrusor muscle activity but excitatory on urethral sphincter (Burgard et al., 2003). It was proposed that 5-HT$_{1A}$ receptors were located on the terminals of sensory afferent fibers to depress neurotransmitter release.

Human Brain Imaging Studies.

In the last decade, the areas of the brain involved in the control of micturition have been examined in human brain imaging studies using single-photon emission computed tomography (SPECT), positron emission tomography (PET), and functional magnetic resonance imaging (fMRI) (DasGupta et al., 2007; Griffiths and Tadic, 2008; Fig. 110.39). All these methods provide indirect measures of regional blood flow, assumed to be related to local neuronal activity, but PET is good for measuring long-lasting states of a system, whereas fMRI is better for following relatively fast events. SPECT has rather poor temporal and spatial resolution.

Cerebral Control of Voiding.

During human voiding the urethral sphincter relaxes, facilitating urine flow, and the detrusor contracts to expel urine. This coordinated relaxation and contraction of urethra and bladder respectively is driven by a long-loop spinobulbospinal reflex (Fowler et al., 2008). As the bladder fills, increasingly strong bladder afferents travel via synapses in the sacral cord to the brainstem and midbrain, where they synapse in the central PAG and possibly Barrington nucleus or PMC. Although there are differing views about how the brainstem circuitry is organized, regardless, if the trigger level is exceeded, efferent signals from the

PMC descend to the sacral cord, where they excite an indirect inhibitory pathway via the nucleus of Onuf that leads to sphincter relaxation (Blok and Holstege, 1998) and an excitatory pathway to the bladder that leads to detrusor contraction; thus voiding occurs. Therefore the spinobulbospinal voiding-reflex pathway functions as a switch, either “off” (storage) or “on” (voiding). In the absence of higher control, this switching behavior would lead to involuntary bladder emptying (i.e., incontinence) whenever the bladder volume reached a critical level sufficient to trigger the brainstem switch.

White-matter damage that causes permanent incontinence appears to do so by disrupting a pathway (from medial frontal cortex to brainstem, either direct or via the thalamus) carrying the signal that maintains continence by tonically inhibiting the voiding reflex during storage. Imaging studies using PET (Athwal et al., 2001; Blok and Holstege, 1997, 1998; Blok et al., 1997, 1998; Matsuura et al., 2002; Nour et al., 2000) or MRI (Blok et al., 2006; Di Gangi Herms et al., 2006; Griffiths et al., 2005; Kunze et al., 2006) are in agreement that during bladder filling, storage, and withholding of urine, there is activity in the right inferior frontal or dorsolateral prefrontal cortex, perhaps extending into the lateral part of the superior frontal cortex. There is some right-sided predominance. In contrast, there is little evidence for activation of the medial parts of the frontal cortex during storage. These observations are consistent with the concept that functional imaging reveals gray-matter activation or deactivation, whereas lesions may damage critical links in white-matter connecting pathways also.

Additional Regions.

PET scan studies in normal men and women revealed that, during voiding, two cortical areas (the dorsolateral prefrontal cortex and anterior cingulated gyrus) were active (i.e., exhibited increased blood flow). The hypothalamus, including the preoptic area, as well as the pons and the PAG also showed activity in concert with voluntary micturition (Blok and Holstege, 1997, 1998; Blok et al., 1997, 1998). Another PET study during voiding also confirmed that micturition was associated with increased activity in the pons, inferior frontal gyrus, hypothalamus, and PAG, while also showing activity in several other cortical areas (postcentral gyrus, superior frontal gyrus, thalamus, insula, and globus pallidus) and the cerebellar vermis (Nour et al., 2000).

Many functional imaging studies have observed responses (mostly activations) in ACG to bladder filling, storage, or withholding (Athwal et al., 2001; Blok and Holstege, 1997, 1998; Blok et al., 1997, 1998; Griffiths et al., 2005; Komesu et al., 2011; Matsuura et al., 2002; Yin et al., 2006). Response to bladder filling in the dorsal ACG and adjacent supplementary motor area (SMA) is abnormally pronounced in patients with urge incontinence (Griffiths et al., 2007) when, with full bladder but without any actual bladder contraction, they experience the abnormal sensation of urgency (a compelling desire to void that is difficult to inhibit [Abrams et al., 2002], also associated with fear of leakage, i.e., embarrassment) (Abrams et al., 1988). Thus urgency is a powerful homeostatic and social emotion that provides strong motivation to void together with motor output aimed at suppressing incontinence until a socially acceptable location can be reached. fMRI observations in rats confirm activation in the cingulate cortex during bladder filling (Tai et al., 2009), although whether this region is homologous with the human dorsal anterior cingulate cortex (dACC) and whether rats ever experience urgency are not known.

The demonstration by Barrington (1925) in the cat that a center necessary for activation of micturition existed at the level of the pons provided the background for recognizing a comparable center in humans and the early report of the association of difficulty with micturition with posterior fossa tumors. Later histories of individual cases of discrete pontine lesions (Betts et al., 1992; Komiyama et al., 1998; Manente et al., 1996; Sakakibara et al., 1996) and reports of difficulties with micturition or retention as a feature of brainstem gliomas in children (Renier and Gabreels, 1980; Ueki, 1960) or vascular lesions (Sakakibara et al., 1996) confirmed the likely existence of a comparable center in humans. Studies using MRI to visualize the precise location of the responsible lesions sited this in the dorsolateral pons, including the pontine reticular nucleus and the reticular formation, adjacent to the medial parabrachial nucleus and locus ceruleus (Sakakibara et al., 1996). Lesions in this location are frequently associated with disturbances of consciousness and respiration, and bladder symptoms may therefore be overlooked.

Other regions relevant to bladder control and revealed only by functional imaging include parts of parietal and frontoparietal cortices, posterior cortex (precuneus, posterior cingulate cortex), parts of the limbic system (hippocampal complex, amygdala), and the cerebellum. Functional imaging has occasionally shown activity in the basal ganglia, particularly the striatum and putamen (Griffiths et al., 2009). Correspondingly, dopamine pathways are thought to have a profound inhibitory effect on the PMC in health that is lost in Parkinson disease (Winge and Fowler, 2006).

Model of Brain-Bladder Control and Normal Continence Mechanism.

The brain regions involved in bladder control are believed to be organized in neural circuits that perform different tasks related to homeostasis, answering questions regarding the adequacy of bladder filling, and the safety and social appropriateness of voiding, as well as the reflex or mechanical aspects dealt with by the brainstem switch. We should therefore expect forebrain control of the switch to involve limbic circuits (concerned with basic emotion and safety) and cortical circuits (concerned with social propriety [Amodio and Frith, 2006] and conscious decision making). In the working model, the PAG and PMC form the brainstem switch (Fig. 110.40). The PMC is the final efferent brain nucleus involved in bladder control. The PAG receives numerous projections from forebrain regions (Mantyh, 1982; Mouton and Holstege, 2000) including the medial and orbital prefrontal cortex (An et al., 1998).

FIG. 110.40 Working model of forebrain control of micturition showing the brainstem switch and neural circuits that mediate two possible continence mechanisms. The normal mechanism *(red)* operates when there is a normal sensation of bladder filling. It depends on tonic inhibition of the brainstem switch via a long return pathway from the medial prefrontal cortex to the brainstem switch (probably via the anterior thalamic radiation but shown for simplicity as a direct connection to the periaqueductal gray [PAG]). The inhibition is switched off for voiding. A backup mechanism *(yellow)* corresponds to the abnormal sensation or urgency. It may operate via brainstem nuclei such as an L-region (pontine storage center) or by modulating the sympathetic input to bladder and urethra. The *dashed blue arrows* show a possible circuit concerned with monitoring safety and/or maintaining continence without conscious sensation. *dACC,* Dorsal anterior cingulate cortex; *HIP,* (para)hippocampal complex (may include amygdala, inferior parts of temporal lobe and parts of posterior cortex); *HYP,* hypothalamus; *INS,* insula; *Lat,* lateral; *L-reg,* L-region; *med,* medial; *PFC,* prefrontal cortex; *PMC,* pontine micturition center; *SMA,* supplementary

motor area; *THAL,* thalamus.

During urine storage, as the bladder fills, it generates afferent signals that are transmitted to the brainstem switch but do not trigger it. They are relayed from the PAG via the thalamus to the insula (red circuit) and, if activation is strong enough, generate a desire to void. Propagation of this insular activity to the lateral and medial prefrontal cortex enables a conscious decision about voiding and an assessment of social propriety and possible embarrassment. If no voiding is planned, a return pathway from the medial frontal cortex to the brainstem tonically suppresses the voiding reflex. The pathway may run directly or via the thalamus in the anterior thalamic radiation. The result is postulated to be the normal continence mechanism. When there is a normal sensation of bladder filling, it exerts negative feedback on the brainstem switch, preventing incontinence. Interruption of the negative feedback—for example, by white-matter damage in the medial prefrontal cortex–periaqueductal gray (mPFC-PAG) pathway—leads to incontinence. During normal daily life, however, there is usually no conscious awareness of the bladder at all.

Pharmacology

Muscarinic Mechanisms

Detrusor strips from normal human bladders are contracted by cholinergic muscarinic receptor agonists and by electric stimulation of intrinsic cholinergic nerves. Contractile responses can be completely abolished by atropine (Sibley, 1984). **There are at least five receptor subtypes based on molecular cloning and four different receptor subtypes based on pharmacology (M_1 to M_5)** (Eglen et al., 1996; Hegde et al., 1997; Somogyi et al., 1994; Wang et al., 1995; Yamaguchi et al., 1996).

Pharmacologically, M_1, M_2, and M_3 receptor subtypes have been found in the human bladder by receptor binding assays (Kondo et al., 1995); **all M_1 to M_5 receptor mRNAs are detected by reverse transcription polymerase chain reaction assays** (Andersson and Wein, 2004; Mansfield et al., 2005). **Although ligand receptor binding studies revealed that M_2 receptors predominate, M_3 receptors mediate cholinergic contractions** (Eglen et al., 1994; Harriss et al., 1995; Hegde et al., 1997; Lai et al., 1998; Yamaguchi et al., 1996). **Stimulation of M_3 receptors by ACh leads to IP_3 hydrolysis as a result of PLC activation and then to the release of intracellular calcium and smooth muscle contraction** (Fry et al., 2002; Harriss et al., 1995) (see Figs. 110.15, 110.17, and 110.18). **The involvement of transmembrane flux of calcium ions through nifedipine-sensitive L-type Ca^{2+} channels has also been indicated in M_3 receptor–mediated detrusor muscle contractions** because the L-type Ca^{2+} channel inhibitor nifedipine strongly suppressed carbachol-induced detrusor contractions, whereas the PLC inhibitor or the store-operated Ca^{2+} channel inhibitor caused little inhibition in rats and humans (Andersson and Arner, 2004; Andersson and Wein, 2004; Frazier et al., 2008; Schneider et al., 2004a, 2004b) (see the earlier section on calcium signaling in detrusor myocyte). However, other studies have indicated the major contribution of the PLC-mediated mechanism to M_3 receptor–induced detrusor contractions, because PLC inhibitors significantly suppressed carbachol-induced detrusor contractions in rats (Braverman et al., 2006a, 2006b), and intracellular calcium elevation after carbachol application was observed without membrane depolarization in human bladders, which is required for the opening of L-type Ca^{2+} channels (Fry et al., 2002). Hashitani et al. (2000) reported that the stimulation of muscarinic receptors activates calcium influx through L-type Ca^{2+} channels and calcium release from intracellular calcium stores in guinea pig bladders.

It has also been proposed (Ehlert et al., 2005; Hegde et al., 1997) that **coactivation of M_2 receptors could enhance the response to M_3 stimulation by (1) inhibition of adenylate cyclase, thereby suppressing sympathetically mediated depression of detrusor muscle; (2) inactivation of K^+ channels; or (3) activation of nonspecific cation channels.** In addition, because the specific ROK inhibitor Y-27632 reportedly suppresses carbachol-induced detrusor contractions in rats and humans, **muscarinic receptor activation in detrusor smooth muscles is likely to stimulate the ROK pathway, leading to a direct inhibition of myosin phosphatase that induces calcium sensitization to enhance the ability of the muscle to generate the same contractile force with lower levels of intracellular calcium** (Andersson and Wein, 2004; Frazier et al., 2008; Schneider et al., 2004a, 2004b). Although the involvement of M_3 receptors for ROK activation has been suggested (Andersson and Arner, 2004; Andersson and Wein, 2004; Schneider et al., 2004a) (see Fig. 110.15), a study has also suggested the participation of M_2 receptors in this mechanism because Y-27632 not only suppressed carbachol-induced muscle contractions but also increased the affinity of darifenacin, an M_3 receptor antagonist with approximately a 30-fold selectivity for M_3 over M_2 receptors, for inhibiting carbachol-induced contractions of rat bladders (Braverman et al., 2006a, 2006b). It has also been reported that the muscarinic receptor subtype–mediated detrusor contractions shift from M_3 to M_2 receptor subtype in certain pathological conditions, such as obstructed or denervated hypertrophied bladders in rats (Braverman and Ruggieri, 2003; Braverman et al., 2006a, 2006b), as well as in bladder muscle specimens from patients with neurogenic bladder dysfunction (Pontari et al., 2004).

Studies using constructed mutant mice lacking the M_3 receptor or the M_2 and M_3 receptors have demonstrated that this subtype plays key roles in salivary secretion, pupillary constriction, and detrusor contractions (Igawa et al., 2004; Matsui et al., 2000, 2002). However, M_3-mediated signals in digestive and reproductive organs are dispensable, probably because of redundant mechanisms through other muscarinic ACh receptor subtypes or other mediators (Matsui et al., 2000). In addition, it has also been found that male M_3 knockout mice had a distended bladder and larger bladder capacity compared with females, indicating a considerable sex difference in the micturition mechanism (Igawa et al., 2004; Matsui et al., 2002). Thus M_3 or M_2 and M_3 double-knockout mice should provide a useful animal model for the DO pathophysiology and pharmacology.

The muscarinic receptor antagonists tolterodine and oxybutynin (Table 110.4) are widely prescribed drugs for urinary incontinence. Oxybutynin is a nonspecific muscarinic antagonist with additional smooth muscle relaxant properties. The smooth muscle relaxation properties of oxybutynin may be clinically relevant only with intravesical instillation of the drug. In addition, botulinum toxin A injections in children and adolescents diagnosed with neurogenic DO are associated with decreased muscarinic receptor muscular expression (Schulte-Baukloh et al., 2013). Thus, because new antimuscarinic and other therapies are continually being developed by the pharmaceutical industry, all urologists should be aware of the existence of muscarinic receptor subtypes and their distribution in the LUT and other organs.

TABLE 110.4

Drugs With Bladder Action

CLASSIFICATION	EXAMPLES	PHARMACOLOGIC ACTION
Anticholinergic agents	Atropine Glycopyrrolate Oxybutynin Propantheline Tolterodine	Inhibit muscarinic receptors, thus reducing the response to cholinergic stimulation; used to reduce pressure during bladder filling and for the treatment of unstable bladder contractions.
Smooth muscle relaxants	Dicyclomine Flavoxate	Direct smooth muscle relaxation reduces intravesical pressure during filling and reduces severity and presence of unstable bladder contractions; most of these agents have some degree of anticholinergic action.
Calcium antagonists	Diltiazem Nifedipine Verapamil	Used in the treatment of unstable bladder contractions to reduce the magnitude of the spikes by reducing the entrance of calcium during an action potential.
Potassium channel openers	Cromakalim Pinacidil	Act to increase the membrane potential and thus reduce the myogenic initiation of unstable bladder contractions.

Prostaglandin synthesis inhibitors	Flurbiprofen	Prostaglandins have been implicated in increased smooth muscle tone and in the induction of spontaneous activity. Inhibition of prostaglandin synthesis could promote relaxation of the bladder during filling and decrease spontaneous activity of the bladder.
β-Adrenergic agonists	Isoproterenol Terbutaline	Stimulation of β-receptors induces relaxation of the bladder body, resulting in a decrease in intravesical pressure during filling.
Tricyclic antidepressants	Amitriptyline Imipramine	These agents have anticholinergic, direct smooth muscle relaxant, and norepinephrine reuptake inhibition properties.
α-Adrenergic agonists	Ephedrine Phenylpropanolamine Midodrine Pseudoephedrine	Increase urethral tone and closure pressure by direct stimulation of α-adrenergic receptors.
Afferent nerve inhibitors	DMSO Capsaicin Resiniferatoxin	Reduce the sensory input from bladder and thereby increase bladder capacity and reduce detrusor overactivity.
Estrogen	Estradiol	Direct application to the vagina or oral therapy may increase the thickness of the urothelial mucosa, making a better seal and reducing the incidence of incontinence. Other actions may include increasing adrenergic effects on the urethra and increasing blood flow.

DMSO, Dimethyl sulfoxide.

We will briefly present two additional issues regarding the effect of antimuscarinic drugs on the bladder and salivary glands that have clinical relevancy. First, antimuscarinic drugs are metabolized, and their metabolites have pharmacologic effects. It has been shown that oxybutynin has less of a dry mouth effect than does its metabolite desethyloxybutynin (Gupta and Sathyan, 1999). Therefore the controlled-release formulation of oxybutynin maintains the efficacy of immediate-release oxybutynin but with significantly fewer side effects. Tolterodine and solifenacin have been shown in cats and rats, respectively, to have less activity on the salivary gland muscarinic receptors than on the bladder muscarinic receptors (Nilvebrant et al., 1997; Ohtake et al., 2004). Second, the site and speed of antimuscarinic metabolism appear to have profound effects in terms of clinical efficacy and side effects.

Muscarinic Selectivity

Pharmacologically defined subtype-selective drugs have been developed. Darifenacin and vamicamide have been demonstrated to be relatively selective for the M_3 subtype (Andersson, 1997; Steers, 2006; Yamamoto et al., 1995). However, they are not necessarily tissue selective, because salivary glands and other tissues also contain M_3 muscarinic receptors. Tolterodine appears to be a muscarinic antagonist that has selectivity for the bladder compared with the salivary gland, even though it may not be an M_3 subtype–selective antagonist (Andersson, 1998; Nilvebrant et al., 1997). Solifenacin has also shown selectivity to the bladder over the salivary gland; the receptor selectivity of solifenacin to M_3 receptors over M_2 receptors (10-fold) is similar to that of oxybutynin (Ikeda et al., 2002; Ohtake et al., 2004). Thus, therapeutically, it is more important to be tissue selective than subtype selective (Andersson, 1998; Nilvebrant et al., 1997). A truly bladder-selective antimuscarinic drug with *no* side effects is the “Holy Grail” of OAB drug therapy.

In addition, a number of studies have indicated that urothelial cells have the ability to release a variety of neurotransmitters including ACh and ATP. Mechanical stimuli and cholinergic agonists can evoke non-neuronal ACh release. Furthermore, stimulating ACh receptors leads to release of ATP, whereas blocking these receptors can reduce this release (Hanna-Mitchell et al., 2007; Mallory et al., 1991; McLatchie et al., 2014). These and other data suggest that release of ACh can modulate the release of additional transmitters that may help to explain in part the mechanism of action for muscarinic antagonists in reducing symptoms of bladder disorders.

Cognitive Impairment With Antimuscarinic Agents

It is well established that the efficacy of antimuscarinics and safety profiles depend upon interaction with a variety of muscarinic subtype receptors, which are expressed throughout the body. However, interactions with the M1 subtype in the CNS have the likelihood, especially in the older adult or those that have other comorbid disorders, that alter lipophilicity and ability to cross the blood-brain barrier, which can lead to cognitive impairment. In addition, combined use of antimuscarinics with drugs that also have anticholinergic activity (such as antihistamines, antispasmodics, and even muscle relaxants) can lead to confusion, mild cognitive deterioration (although not at risk for dementia), and even in some cases delirium in the older adult. Studies have revealed that anticholinergic withdrawal is likely to improve central side effects even after only a few weeks. It is important to be cautious with antimuscarinics in treating bladder symptoms in the elderly and frail patient, and even more so in those with pre-existing dementia (De Ridder, 2006; Moga et al., 2017; Wagg et al., 2010). This topic is discussed further in the section on aging as related to clinical relevance.

Key Points: Muscarinic Mechanisms

- There are at least five muscarinic receptor subtypes. Pharmacologically, M_1, M_2, and M_3 receptor subtypes have been found in the human bladder.
- Stimulation of M_3 receptors by ACh induces calcium influx through L-type Ca^{2+} channels, as well as IP_3 hydrolysis as a result of PLC activation, resulting in the release of intracellular calcium, both of which contribute to a smooth muscle contraction.
- Muscarinic receptor subtype–mediated detrusor contraction shift from M_3 to M_2 receptor subtype has been reported in bladder muscle specimens from neurogenic bladder dysfunction patients.

Adrenergic Mechanisms

β-Adrenergic Receptors

Stimulation of β_2- and β_3-adrenergic receptors that exist in the human detrusor results in the direct relaxation of the detrusor smooth muscle (Andersson, 1993; Levin and Wein, 1995; Morita et al., 1993; Nishimoto et al., 1995). In addition, β-adrenergic–stimulated relaxation is mediated through the stimulation of adenylate cyclase and the accumulation of cAMP (Andersson, 1993; Andersson and Arner, 2004; Levin et al., 1986). Because β-adrenoceptor–mediated relaxation of the human detrusor was not blocked by selective β_1– or β_2-adrenoceptor antagonists, such as dobutamine and procaterol, but was blocked by selective β_3-adrenoceptor antagonists, **the relaxation induced by adrenergic stimulation of the human detrusor is mediated mainly through β_3-adrenoceptor activation** (Andersson and Arner, 2004; Igawa et al., 1999; Yamaguchi, 2002). A quantitative analysis by reverse transcription polymerase chain reaction has also confirmed that the β_3-adrenergic receptor is the most highly expressed subtype among α- and β-adrenoceptor subtypes at the mRNA level in human bladders (Nomiya and Yamaguchi, 2003).

For these and other reasons, the β_3-receptor agonist mirabegron has been approved as a new treatment option for OAB with symptoms of urge incontinence (Andersson and Arner, 2004; Bridgeman et al., 2013). This agent has been shown to provide an alternative for patients with contraindications or intolerance to existing therapy, although combination therapy (mirabegron and the antimuscarinic solifenacin) has also been shown to be effective (Abrams et al., 2015). The mechanism of action may be related to effects on a number of cell types, including bladder afferent activity (Aizawa et al., 2015). Findings in rodents have revealed that β_3-adrenoceptor stimulation with mirabegron increased bladder compliance and shortened the intervoid interval; this regulation may be a result of the effect at a number of sites, including reduction of nonmicturition contractions and decreased afferent nerve activation (Aizawa et al., 2015; Sadananda et al., 2013).

A second pharmacologic method of increasing levels of cyclic nucleotide monophosphates (cAMP or cGMP) is use of PDE inhibitors. PDE enzymes catalyze the hydrolysis of cAMP or cGMP (Andersson, 1997; Longhurst et al., 1997; Rahnama'i et al., 2013). There are several classes of PDEs that have individual substrate affinities, specific species, tissue distributions, and pharmacologic selectivities (Longhurst et al., 1997; Truss et al., 1996). Currently, there is considerable research trying to identify the specific isoform of PDE present in the bladder as opposed to that in the penis (Truss et al., 1996). For example, in the isolated guinea pig bladder, the frequency of agonist-induced phasic activity is slowed by cAMP, and degradation of intracellular cAMP in the cells responsible for phasic activity appears to involve primarily PDE4 (Gillespie, 2004). PDE4 inhibitors are shown to suppress DO in a rat model of BOO induced by partial urethral ligation (Kaiho et al., 2008). Although a number of preclinical studies have been done, the PDE1 and PDE5 inhibitors have been used clinically for management of storage or voiding disorders.

α-Adrenergic Receptors

Although α-adrenergic stimulation is not prominent in the normal bladder, evidence indicates that under pathological conditions, such as DO associated with BOO, the α-adrenergic receptor density, especially the α_{1D}-receptor subtype, can increase to such an extent that the norepinephrine-induced responses in the bladder are converted from relaxation to contraction (Andersson and Arner, 2004). In rats with outflow obstruction, the proportion of α_{1D}-receptor subtype in the total α_1-receptor mRNA in the bladder is increased to 70% from 25% in normal rat bladders (Hampel et al., 2002), and urinary frequency is suppressed by an inhibition of α_{1D} and α_{1A} receptors by tamsulosin, whereas α_{1A}-receptor suppression by 5-methyl-urapidil has no effect. Moreover, α_{1D}-receptor knockout mice have larger bladder capacity and voided volumes than do their wild-type controls, which supports an important role of α_{1D} receptors in the control of bladder function (Chen et al., 2005). However, in humans, there is the predominant expression of α_{1D} receptors already in the normal bladder (Malloy et al., 1998), and the level of expression of α-adrenoceptor mRNA, which is considerably low compared with β_3 adrenoceptors in normal bladders, was not increased in the bladder with outflow obstruction (Nomiya and Yamaguchi, 2003). Thus the contribution of α_{1D} receptors to DO observed in a variety of pathological conditions, including obstructive uropathy and incontinence, still must be established (Andersson and Arner, 2004).

α-Adrenergic mechanisms are more important in urethral function. Substantial pharmacologic and physiologic evidence indicates that **urethral tone and intraurethral pressure are influenced by α-adrenergic receptors.** The presence of α_1 and α_2 adrenoceptors has been shown in the urethra of various species including humans. Among α_1 adrenoceptors, **the α_{1A} adrenoceptor is the major subtype expressed in urethral smooth muscle** at the mRNA and protein levels (Michel and Vrydag, 2006; Yono et al., 2004). Isolated human urethral smooth muscle contracts in response to α-adrenergic agonists (Awad et al., 1978; Mattiasson et al., 1984; Nordling et al., 1981; Yalla et al., 1977). It is also reported in the rabbit that the urethral contraction is mediated by the α_{1A}-adrenoceptor subtype (Michel and Vrydag, 2006; Testa et al., 1993). Likewise, **hypogastric nerve stimulation and α-adrenergic agonists raise intraurethral**

pressure, which is blocked by α_1-adrenergic antagonists (Awad et al., 1976; Yalla et al., 1977). These findings provide the rationale for use of α-adrenergic agonists to promote urine storage by increasing urethral resistance.

Conversely, α-adrenergic receptor antagonists facilitate urine release in conditions of functionally increased urethral resistance, such as benign prostatic hyperplasia (BPH). Although the α_{1A}-adrenoceptor is the major subtype in the prostate and urethra, highly selective α_{1A}-adrenoceptor antagonists (e.g., RS-17053) do not alter LUTS scores in men with BPH, but these agents are effective at relaxing prostate smooth muscle and increasing urine flow in men (Schwinn and Roehrborn, 2008). In contrast, α_1-adrenoceptor antagonists that contain α_{1D}-adrenoceptor blocking activity improve bladder-based symptoms in humans (Nishino et al., 2006), suggesting the important role of the α_{1D}-adrenoceptors for storage symptoms associated with BOO, receptors potentially located at the bladder or the spinal cord (Schwinn and Roehrborn, 2008).

α_2-Adrenergic antagonists increase the release of norepinephrine from urethral tissues through a presynaptic mechanism, but this does not affect the contractility of urethral smooth muscle in vitro (Mattiasson et al., 1984; Michel and Vrydag, 2006; Willette et al., 1990). The human urethra lacks postjunctional α_2-adrenergic receptors, although in vitro prejunctional activation of these receptors produces a feedback inhibition of norepinephrine release. Pharmacologic and electrophysiologic data suggest that adrenergic nerves influence excitatory cholinergic transmission in pelvic ganglia. Investigators (de Groat and Booth, 1993) have shown in the cat that hypogastric nerves inhibit excitatory cholinergic transmission in vesical ganglia by activation of α_2-adrenergic receptors (Fig. 110.41). Conversely, β-adrenergic agonists facilitate transmission in vesical ganglia.

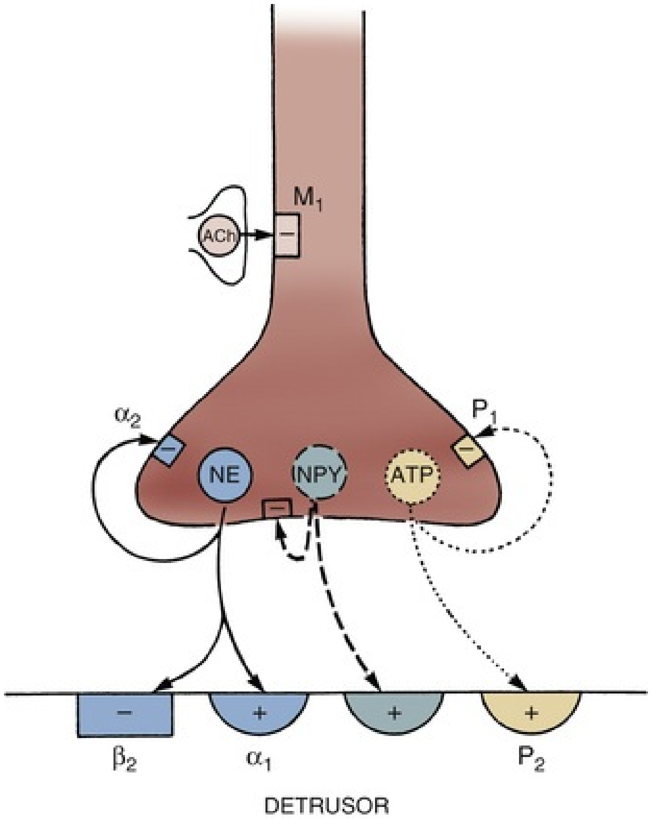

FIG. 110.41 Diagram of possible transmitters in an adrenergic terminal supplying the bladder or urethra. Norepinephrine (NE) release can activate α_1-adrenergic receptors and produce contraction (+) or β receptors and cause relaxation (−) of the detrusor. Feedback inhibition of NE release through α_2 receptors can also occur. Neuropeptide Y (NPY) can produce smooth muscle contraction (+) or inhibit acetylcholine (ACh) release (not shown), or feedback can inhibit NE release. Adenosine triphosphate (ATP) can activate P_2 receptors in the detrusor, which elicit contraction (+) or inhibit (−) further ATP release through P_1 prejunctional receptors. ACh release from terminals in synaptic contact with an adrenergic varicosity can inhibit firing of adrenergic axons by activation of M_1 receptors.

Key Points: Adrenergic Mechanisms

- β-Adrenergic–stimulated relaxation is mediated through the activation of adenylate cyclase and the accumulation of cAMP.
- The β_3-adrenergic receptor is the most highly expressed subtype among α- and β-adrenoceptor subtypes, and β_3-receptor agonists are in clinical trials for treatment of DO.

- In the human, there is a predominant expression of α_{1D}-receptors present in the normal bladder, and the level of expression of α-adrenoceptor mRNA, which is considerably low compared with β_3-adrenoceptors in normal bladders, was not increased in the bladder with outflow obstruction.
- Urethral tone and intraurethral pressure are influenced by α-adrenergic receptors. The α_{1A}-adrenoceptor is the major subtype in the prostate and urethra, and all three α_1-adrenoceptor subtypes (α_{1A}, α_{1B}, α_{1D}) are present in blood vessels.

Urethral Tone in Women

Taki et al. (1999) separated the entire length of the human female urethra into several parts and studied the regional contractile effect of norepinephrine, clonidine, ACh, and potassium chloride. Their findings suggest that sympathetic innervation helps maintain resting urethral tonus, mainly through α_1-adrenoceptors. With identification of at least three distinct subtypes of α_1 adrenoceptors with distinct pharmacologic profiles, it may be possible to develop urethra-specific adrenergic agonists for the treatment of stress urinary incontinence (SUI). A small-scale, placebo-controlled clinical study has demonstrated that activation of the $\alpha_{1A/1L}$-adrenoceptor subtype, which is a pharmacologic isoform of the α_{1A}-adrenoceptor gene product, was effective in reducing the number of incontinence episodes in women with mild-to-moderate SUI (Musselman et al., 2004), suggesting an important role of α_1-adrenoceptors in the urethral continence mechanism, although the data are still preliminary.

Afferent Neuropeptides

Afferent neurons innervating the LUT exhibit immunoreactivity for various neuropeptides, such as SP, CGRP, pituitary adenylate cyclase–activating polypeptide (PACAP), leucine enkephalin, CRP, and VIP (De Groat, 1986; Keast and De Groat, 1992; Maggi, 1993; Vizzard, 2001, 2006), as well as growth-associated protein-43 (GAP43), NOS (Vizzard et al., 1996), glutamic acid, and aspartic acid (Keast and Stephensen, 2000). These substances have been identified in many species and at one or more locations in the afferent pathways including (1) afferent neurons in lumbosacral DRG, (2) afferent nerves in the peripheral organs, and (3) afferent axons and terminals in the lumbosacral spinal cord (Kawatani et al., 1985, 1986, 1996; Morrison and Birder, 2005). The majority (>70%) of bladder DRG neurons in rats appear to contain multiple neuropeptides; CGRP, SP, and PACAP are the most common. In cats, VIP is also contained in a large percentage of bladder DRG neurons (de Groat, 1987).

Many of these peptides, which are contained in capsaicin-sensitive, C-fiber bladder afferents, are released in the bladder by noxious stimulation and contribute to inflammatory responses by triggering plasma extravasation, vasodilation, and alterations in bladder smooth muscle activity (Ishizuka et al., 1994, 1995; Maggi, 1993). These agents also function as transmitters at afferent terminals in the spinal cord.

Tachykinins

The tachykinins are a family of small peptides sharing a common C-terminal sequence, Phe-Xaa-Gly-Leu-Met-NH_2, whose main members are **SP, neurokinin A, and neurokinin B.** Tachykinins are found in central and peripheral nervous systems. In the peripheral nerves, tachykinins are predominantly located in the terminals of nonmyelinated, sensory C fibers. **The diverse biologic effects of the tachykinins are mediated through three receptors, designated NK_1, NK_2, and NK_3,** which belong to the superfamily of seven transmembrane-spanning G protein–coupled receptors (Khawaja and Rogers, 1996). SP is the most potent tachykinin for the NK_1 receptor, whereas neurokinin A exhibits the highest affinity for the tachykinin NK_2 receptor, and neurokinin B for the tachykinin NK_3 receptor (Table 110.5). All receptor subtypes have been identified in the bladder of humans and animals such as rats, mice, and dogs (Andersson and Arner, 2004; Lecci and Maggi, 2001).

TABLE 110.5

Tachykinins and Tachykinin Receptors

TACHYKININ	RECEPTOR
Substance P	NK_1
Neurokinin A	NK_2
Neurokinin B	NK_3

Tachykinins released from capsaicin-sensitive sensory C fibers in response to irritation in the bladder can act on (1) NK_1 receptors in blood vessels to induce plasma extravasation and vasodilation, (2) NK_2 receptors to stimulate bladder contractions, and (3) NK_2 receptors on primary afferent terminals to increase the excitability during bladder filling or during bladder inflammation (Andersson, 1993; de Groat, 1987; Lecci and Maggi, 2001; Morrison et al., 1995). A study by Kamo et al. (2005) also demonstrated that activation of NK_3 receptors on capsaicin-sensitive C-fiber afferents in the rat bladder can increase the excitability during bladder filling.

Intrathecal administration of NK_1 antagonists (RP 67580 and CP 96345) or systemic application of centrally acting NK_1 antagonists (GR 205171 and CP 99994) increased bladder capacity in normal rats and guinea pigs, respectively, without changing voiding pressure, whereas NK_2, NK_3, or peripherally acting NK_1 antagonists were ineffective (Lecci et al., 1993; Yamamoto et al., 2003). DO in rats induced by chemical cystitis, intravesical administration of capsaicin, or intravenous injection of L-dopa was also suppressed by intrathecal injection of NK_1 antagonists (Ishizuka et al., 1994, 1995; Lecci et al., 1994). DO induced by capsaicin was reduced by an NK_2 antagonist (SR 48965) that did not influence normal voiding (Lecci et al., 1997). In anesthetized guinea pigs, TAK-637, an NK_1 receptor antagonist, administered orally or intravenously also increased the volume threshold for inducing micturition and inhibited the micturition reflex induced by capsaicin applied topically to the bladder (Doi et al., 1999). In a clinical study, an NK_1 receptor antagonist, aprepitant, has also been shown to effectively decrease the average daily number of micturitions and urgency episodes compared with placebo at 8 weeks in women with idiopathic OAB (Green et al., 2006). These results indicate that **sensory input to the spinal cord from non-nociceptive bladder afferents is mediated by tachykinins acting on NK_1 receptors, whereas input from nociceptive afferents in the bladder can be mediated by NK_1, NK_2, and NK_3 receptors.** In addition, tachykinin NK_3 receptor activation in the spinal cord can inhibit the micturition reflex through an activation of the spinal opioid mechanism (Kamo et al., 2005).

Autofeedback mechanisms may also be important at afferent nerve terminals. As mentioned earlier, some stimuli are known to release neuropeptides from afferent nerves, and these neuropeptides may, in turn, sensitize the afferents. NK_2 agonists were found (Bushfield et al., 1995) to sensitize bladder mechanoreceptors by acting on NK_2 autoreceptors in the sensory endings in the bladder mucosa to produce the combination of effects found previously for other sensitizing agents (Morrison et al., 1998). The NK_2 receptor blocker SR 48968 decreases the sensitivity of bladder mechanoreceptors and also blocks the sensitization produced by NK_2 agonists and high urinary potassium levels. This suggests that the sensitization produced by intravesical chemical stimuli may be caused by a mechanism using the NK_2 receptor. On the basis of these findings, it could be hypothesized that high urinary potassium concentration or higher levels of bladder distention release neurokinin A from sensory endings, and that the sensitization is the result of the action of the peptide on local NK_2 autoreceptors on the sensory endings. It has also been shown that sensory neurons obtained from rat DRG can be excited by NK_2 agonists and inhibited by NK_3 agonists through modulation of Ca^{2+} channel activity mediated by PKC activation (Sculptoreanu and de Groat, 2003). NK_2 receptor activation also leads to PKC-induced phosphorylation of TRPV1 channels, resulting in an increase in capsaicin-evoked currents in rat DRG neurons (Sculptoreanu and de Groat, 2007; Sculptoreanu et al., 2008).

Prostanoids

Prostanoids (prostaglandins and thromboxanes), which make up a family of oxygenated metabolites of arachidonic acid, by the enzymatic activity of cyclooxygenases 1 and 2, are manufactured throughout the LUT and have been implicated in bladder contractility, inflammatory responses, and neurotransmission. Biopsy specimens of human bladder mucosa contain PGI_2, PGE_2, $PGE_{2\alpha}$, and thromboxane A. **In decreasing order of potency, $PGF_{2\alpha}$, PGE, and PGE_2 contract the human detrusor** (Andersson, 1993; Andersson and Arner, 2004). The actions of prostanoids are mediated by specific receptors on cell membranes. The receptors include the DP, EP, FP, IP, and TP receptors that preferentially respond to PGD_2, PGE_2, $PGF_{2\alpha}$, PGI_2, and thromboxane A_2, respectively. Furthermore, EP is subdivided into four subtypes: EP_1, EP_2, EP_3, and EP_4 (Breyer et al., 2001, 2003). **The slow onset of action for these substances suggests a modulatory role for prostaglandins. Some prostaglandins may affect neural release of transmitters, whereas others inhibit acetylcholinesterase activity.** These actions provide mechanisms whereby prostaglandins could potentially augment the amplitude of cholinergic-induced detrusor contractions (Borda et al., 1982).

Attempts to use prostaglandins to facilitate voiding have had mixed

results. Intravesical PGE_2 has been shown to enhance bladder emptying in women with urinary retention and patients with neurogenic voiding dysfunction (Bultitude et al., 1976; Tammela et al., 1987; Vaidyanathan et al., 1981). Others have failed to find PGE_2 useful to facilitate complete evacuation of the bladder (Delaere et al., 1981; Wagner et al., 1985). Intravesical PGE_2 does produce urgency and involuntary bladder contractions (Schussler, 1990). Consistent with this finding, inhibition of prostaglandin synthesis with indomethacin reduces DO (Cardozo and Stanton, 1980).

Endothelins

Endothelins (ETs), a family of 21–amino acid peptides (originally isolated from bovine aortic endothelial cells), include ET-1, ET-2, and ET-3, which are encoded by separate genes and mediate a variety of biologic actions through two distinct G protein–coupled receptor subtypes, the endothelin-A (ET_A) and the endothelin-B (ET_B) receptor (Masaki, 2004; Yanagisawa et al., 1988). The ET_A receptor subtype has a higher affinity for ET-1 and ET-2 than for ET-3; the ET_B receptor subtype binds all ETs with equal affinity (Rubanyi and Polokoff, 1994). ET-1, which is known to be primarily produced by human endothelial cells, can induce prolonged contractile responses in isolated urinary bladder muscle strips in various species (Khan et al., 1999; Maggi et al., 1990). In humans and rabbits, ET-like immunoreactivity is identified in almost all cell types in the bladder, including bladder epithelium, vascular endothelium, detrusor, and vascular smooth muscles, and fibroblasts; **it plays a role in control of bladder smooth muscle tone, regulation of local blood flow, and bladder wall remodeling in pathologic conditions** (Saenz de Tejada et al., 1992). In a rabbit model of BOO, ET-1 and ET_A receptor binding sites in detrusor smooth muscle and urothelium, as well as ET_B receptor binding sites in detrusor smooth muscle, were significantly increased (Khan et al., 1999). In addition, the ET-converting enzyme inhibitor WO-03028719, which suppresses ET-1 production, can improve voiding efficiency and suppress DO in a rat model of BOO (Schroder et al., 2004). YM598, a selective ET_A receptor antagonist, also reduces DO in urethral obstructed rats (Ukai et al., 2006). These results suggest that **the increase in ET-1 expression and ET receptors could be involved in detrusor hyperplasia and overactivity seen in patients with BOO resulting from BPH.**

There is also evidence that ETs have a role in modulation of sensory

function in the peripheral nervous system and CNS. The activation of ET_A receptors in capsaicin-sensitive C-fiber afferents in the bladder induces DO, whereas ET_A receptor activation in the spinal cord can inhibit the micturition reflex through activation of a spinal opioid mechanism in rats (Ogawa et al., 2004). In spinal cord–injured rats, the bladder ET-1 level was increased, and the application of ABT-627, an ET_A antagonist, suppressed C fiber–mediated DO. Accordingly, modulation of ET_A receptor activity in bladder afferent pathways or the spinal cord could be effective in treating bladder overactivity or painful conditions (Ogawa et al., 2008).

Sex Steroids

Differences in responses of human and animal bladders to the effect of drugs suggest that sex steroids play a role in detrusor contractility. It is not unusual for women to note changes in voiding, bladder pain, or continence at different times of their menstrual cycle. **Sex steroids do not directly affect bladder contractility, but they modulate receptors and influence growth of bladder tissues.** Estrogen receptors are expressed by the trigone in women (Iosif et al., 1981). Levin et al. (1980) noted that bladder body muscle from young female rabbits treated with estrogens exhibits increased responsiveness to α-adrenergic, cholinergic, and purinergic agonists. Others have seen a decreased density of adrenergic and muscarinic receptors in the bladder after estrogen administration (Batra and Andersson, 1989; Shapiro, 1986). In contrast to the study by Levin et al. (1980), Elliott et al. (1992) showed that bladder smooth muscle from estrogen-treated rats exhibited decreased contractions.

Estrogens also increase adrenergic receptors in the urethra (Callahan and Creed, 1985). Ekstrom et al. (1993) reported that estrogen administration to ovariectomized rabbits unmasked contractile responses to α-adrenergic agonists, whereas contracted and normal rabbit bladders demonstrated no response to these agents. Some clinicians have combined these agents to elevate urethral pressure in patients with stress incontinence (Wilson et al., 1987). However, the clinical efficacy of the combined use of estrogen with α-agonists has been questioned (Walter et al., 1990). **The effect of estrogens on urinary continence in females probably reflects the multiple actions of this hormone on adrenergic receptors, vasculature, and urothelium. In addition, progesterone increases electrical and cholinergic contractions of the**

bladder. Exogenous estrogens and progesterones also induce NOS activity in bladders of female guinea pigs (Ehren et al., 1995). This effect is postulated to contribute to relief of DO with hormonal treatment. However, the use of estrogens alone to treat either SUI or urgency incontinence has given disappointing results (Abrams et al., 2005), and studies have suggested that estrogen may be associated with an increase in urinary incontinence in postmenopausal women (Hendrix et al., 2005).

Androgen treatment in the male rat has been reported to have similar effects on synaptic connections, as well as effects on motoneuronal somatic and dendritic size in the androgen-sensitive motoneurons innervating the bulbocavernosus and levator ani muscles of the rat (Jordan, 1997; Matsumoto, 1997). Testosterone treatment can also influence the size of postganglionic neurons in the major pelvic ganglion of the male rat (Keast and Saunders, 1998). Thus further studies are needed to evaluate the influence of changes in hormonal environment on the neural pathways controlling the LUT.

Clinical Relevance

The following section discusses different LUTD conditions encountered by urologists that involve perturbation of the physiologic mechanisms presented in this chapter. Some of these conditions arise as a result of injuries to innervation, obstruction, or infection of the LUT. On a logical level, the ideal treatment for these conditions would be to reverse the neurologic injury, relieve the obstruction, or eradicate the infection. When LUTD, manifesting with LUTS, increased postvoid residual (PVR) volume, and/or DO, has no identifiable pathology, then the treatment becomes empirical and driven primarily by LUTS relief. A variety of diagnostic terms have been used to describe idiopathic LUTD conditions: OAB, IC/PBS, and underactive bladder to name a few. **Many of these idiopathic LUTD conditions reflect an increased or augmented sensory input from the LUT, leading to the term *afferent neurourology* in describing these conditions** (Clemens, 2013). Although idiopathic nonobstructive urinary retention (underactive detrusor) may be primarily a failure of efferent signaling, the resultant decreased motor sensory pathway (Eastham and Gillespie, 2013) could exacerbate or prolong this condition. **The ability to augment or inhibit sensory afferent mechanisms in treating these afferent neurourologic conditions could advance treatment for LUTD.**

One overarching paradigm to explain afferent neurourologic conditions involves C-fiber afferent activation via neurotrophic cytokine, such as nerve growth factor (NGF), signaling. Changes in bladder innervation orchestrated by neurotrophins manufactured by detrusor smooth muscle are temporally linked with DO (Fig. 110.42). The ability of local anesthetics, intravesical afferent neurotoxins, and destruction of afferent nerves in the bladder neck and prostate to reduce urgency, frequency, and urgency incontinence indicates an important role for afferent-evoked reflexes (Chalfin and Bradley, 1982). The development of a spinal reflex (ice-water test response) in patients with neurogenic bladders (Geirsson et al., 1999), as well as in patients with BOO (Chai et al., 1998; Hirayama et al., 2003, 2005), suggests a common underlying plasticity in nerves supplying the bladder. Moreover, the association between elevated blood pressure and LUTS in patients with BPH (Pool, 1994; Sugaya et al., 2003) provides a link between changes in sympathetic tone and voiding complaints.

FIG. 110.42 Possible mechanisms underlying plasticity in bladder reflex pathways induced by various pathologic conditions. Bladders from rats with chronic spinal cord injury, urethral obstruction, chronic inflammation, and bladder denervation and those that are spontaneously hypertensive exhibit increased level of neurotrophic factors (NTFs), such as nerve growth factor. NTFs can increase the excitability of C-fiber bladder afferent neurons and alter reflex mechanisms in parasympathetic excitatory pathways in the pelvic nerve (PN), as well as in sympathetic pathways in the hypogastric nerve (HGN). These reflex circuits are organized in the spinal cord as positive-feedback loops that induce involuntary bladder activity. In certain situations, such as the spontaneously hypertensive rat, peripheral efferent mechanisms are also altered: excitatory α_1-adrenoceptor mechanisms are upregulated, providing an additional excitatory input to the bladder.

Mechanisms of Idiopathic Detrusor Overactivity and Overactive Bladder

The classic model of OAB is that of urodynamically demonstrated DO, although **DO was found in only 11% of a contemporary cohort of subjects with OAB symptoms** (Diamond et al., 2012). Nevertheless, various models have been used to explore the pathogenesis of DO and to formulate treatments for urgency incontinence associated with OAB. Animal models for DO that do not involve damage or injury to bladder, urethra, or spinal cord include the **spontaneously hypertensive rat** (Steers et al., 1999), **serotonin reuptake transporter knockout** (Cornelissen et al., 2005), **constitutive BK channel knockout**

(Meredith et al., 2004), **urothelially restricted NGF knock-in** (Schnegelsberg et al., 2010), and **urothelially restricted β_1-integrin knockout** (Kanasaki et al., 2013). Other molecular targets, using transgenic animals, have been used to study LUT function, although none of these models has specifically addressed the clinical problem of DO or OAB. These animal models include knockout mice lacking muscarinic receptors (M_1 to M_5) (Igawa et al., 2004; Matsui et al., 2002), purinergic receptors ($P2X_2$, $P2X_3$) (Cockayne et al., 2000, 2005), and TRPV1 (Birder et al., 2002). With some of these models, a mechanistic theme is alterations in growth factors leading to plasticity in micturitional neural and smooth muscle contractile pathways.

NGF has been a biomarker for LUTD since the description of NGF upregulation by bladder smooth muscle after BOO and increased diuresis (Steers and Tuttle, 2006; Steers et al., 1991). The role of increased urinary NGF as a biomarker for OAB has been studied (Liu and Kuo, 2012; Liu et al., 2009, 2011; Seth et al., 2013). Although the source of the urinary NGF is uncertain, it is less likely to come from the bladder stroma because of the necessity of NGF having to traverse the lamina propria and the entire urothelium. However, the role of increased NGF expressed by the bladder urothelium in mediating a change in bladder function was studied in transgenic mice with overexpression of NGF restricted to the urothelium (Schnegelsberg et al., 2010). These animals had increased urinary frequency, pelvic pain, and prominent neuronal hypertrophy in the lamina propria. Investigators failed to detect increased urothelial tissue NGF in DO subjects and paradoxically less urothelial tissue NGF in subjects with increased urinary frequency (Birder et al., 2007b). It remains to be seen how NGF can be used in evaluation, phenotyping, and/or treatment of OAB, and further studies are needed (Ochodnicky et al., 2011).

Urothelial dysfunction associated with idiopathic OAB has also been studied using human urothelial cells grown in culture. The findings from using human cells in these in vitro studies included increased urothelial polyamine signaling (Li et al., 2013) leading to block of urothelial BK channels (Li et al., 2009). Other findings include increased TRPV1 signaling in the cultured OAB cells (Li et al., 2011). Whether these urothelial abnormalities related to altered bladder urothelial-afferent signaling remains to be seen.

Investigators found that subjects with OAB and urgency incontinence had decreased urethral afferent function (Kenton et al., 2007, 2010) when measured with urethral current perception threshold (CPT) testing. Furthermore, 2 weeks after successful sacral neuromodulation treatment, urethral CPT measures did not change (Gleason et al., 2013). These findings are counterintuitive because augmented urethral afferent function would be expected in OAB. An animal model in which urethral afferent signaling can be selectively modulated (augmented or diminished) would help shed light on the impact of urethral afferent signaling on micturitional behavior.

The role of bladder smooth muscle pathophysiology in OAB and DO has also been studied. **In the constitutive BK knockout mouse, development of OAB micturitional behavior phenotype was seen** (Meredith et al., 2004). The ability to obtain detrusor smooth muscle strips in idiopathic urgency incontinence patients is limited, so confirmation of this phenomenon would be difficult, unlike the case of neurogenic DO (see the next section). Other investigators have examined derangements in regulation of $(Ca^{2+})_i$ from detrusor myocytes isolated from idiopathic and neurogenic DO subjects (Sui et al., 2009). These investigators found that myocytes from DO had increased resting $(Ca^{2+})_i$ and more spontaneous increases in $(Ca^{2+})_i$ arising from influx of extracellular Ca^{2+} from L-type and T-type VDCCs. There was a suggestion that neurogenic DO had greater dysregulation of $(Ca^{2+})_i$ than IDO.

The role of suburothelial myofibroblasts has been also explored in OAB. Immunofluorescent studies of these myofibroblasts from idiopathic and neurogenic DO subjects revealed increased gap junction (Cx43) expression in the myofibroblasts (Roosen et al., 2009). Furthermore, these changes were not reversed, even with successful treatment with onabotulinumtoxinA (OBTX). The links among myofibroblasts; detrusor myocytes; cytokines including interleukin-4 (IL-4), IL-6, IL-10; tumor necrosis factor-α (TNF-α); and transforming growth factor-β1 (TGF-β1); and Cx43 were investigated (Heinrich et al., 2011). These investigators found that these cytokines increased expression of Cx43 in myofibroblasts and myocytes, suggesting a mechanism for increased cellular connectivity in OAB (and IC/PBS) that is related to these cytokines. Although NGF was not tested in this study, investigators using PC12 cells (neuronal cells) found that NGF increased Cx43 connectivity in these cells (Cushing et al., 2005), which suggests that NGF could possibly also increase Cx43 expression in detrusor myocytes and myofibroblasts.

Stress Urinary Incontinence

Traditionally, SUI in women has been thought to be a urethral anatomic and not a urethral physiologic problem. The urethral integral theory of Petros and Ulmsten (1993) led to the development of the mid-urethral sling, the current standard surgical treatment for SUI. However, SUI in women is unlikely to be caused only by anatomic laxity of the anterior vaginal wall. **DeLancey** (2010) **presented data that showed intrinsic sphincteric function (physiologic function) to be more important for maintenance of stress continence than anatomic integrity (anatomic support)**. Pathophysiologic studies of urethral function in women have centered on the mechanisms surrounding urethral injury at time of childbirth using vaginal distention animal models, including pudendal nerve injuries (Damaser et al., 2007; Pan et al., 2009). Chemokines and receptors involved in stem cell homing, such as CCL7, CXCR4, CXCL12, CD195, and CD193, were upregulated with vaginal distention or after vaginal birth in rats (Lenis et al., 2013). Increased expression of monocyte chemotactic protein-3 (MCP-3) at the urethra after vaginal distention provides a homing signal for stem cells, because MCP-3 is a stem cell homing chemokine (Woo et al., 2007). A possible method to diminish SUI after childbirth is to maximize healing of urethral injuries (muscular and neurologic) soon after childbirth.

The ability to use biomarkers to predict success or failure after mid-urethral slings was studied (Chai et al., 2014). This study found that higher urinary NTx (N-telopeptide cross-linked collagen) was associated with a significantly higher failure rate after slings. NTx is a marker for bone metabolism; higher NTx levels reflect greater bone turnover and osteoporosis (Garnero, 2008). It remains to be seen whether leveraging this knowledge can reduce the failure rate of mid-urethral slings, which at 1 year is about 23% (Richter et al., 2010).

Serotonin-norepinephrine reuptake inhibitors, such as duloxetine, increase efferent output at the Onuf nucleus at the sacral spinal cord, thus increasing urethral smooth muscle tone and decreasing SUI (Thor and Katofiasc, 1995). Clinical trials of duloxetine have shown benefits over placebo in treating mild to moderate SUI (Millard et al., 2004; van Kerrebroeck et al., 2004). Duloxetine is approved in Europe, but not the United States, for use in SUI. Duloxetine has also been studied in male postprostatectomy SUI and was found to have statistically significant efficacy over placebo, although the sample size was small (Cornu et al., 2011).

Spinal Cord Injury and Neurogenic Detrusor Overactivity

Damage to the spinal cord above the sacral spinal level results in DO (Chancellor, 1997; Kaplan et al., 1991). Acute spinal cord injury disrupts normal supraspinal circuits that control urine storage and release. **After the spinal shock period of urinary retention** that typically lasts a few weeks, **neurogenic DO develops.** Electrophysiologic data reveal that **this DO is mediated by a spinal micturition reflex that emerges in response to a reorganization of synaptic connections in the spinal cord** (Araki and de Groat, 1997; De Groat, 1975; de Groat et al., 1981, 1990; Yoshimura, 1999). **In addition, bladder afferents that are normally unresponsive to low intravesical pressures become more mechanosensitive, leading to the development of DO.**

Normal micturition is associated with a spinobulbospinal reflex mediated by lightly myelinated Aδ afferents (de Groat and Booth, 1993; DeGroat et al., 1975; de Groat et al., 1993). **These fibers represent only 30% of bladder afferents in some species. Compared with Aδ fibers, the more prevalent unmyelinated C fibers are relatively insensitive to gradual distention of the urinary bladder, at least in the cat** (Habler et al., 1990). Most C fibers in this species remain silent during normal filling of the bladder, although in the rat, some studies indicate that C fibers can fire at low pressures (Sengupta and Gebhart, 1994). **After spinal cord injury, a capsaicin-sensitive C-fiber–mediated spinal reflex develops** (see Fig. 110.25)**. These C-fiber afferents are thought to play a role in the development of DO after spinal cord injury. Capsaicin-sensitive C fibers have also been implicated in DO after upper motoneuron diseases, such as spinal cord injury and multiple sclerosis** (Fowler et al., 1992, 1994; Geirsson et al., 1995; Szallasi and Fowler, 2002). Studies in multiple sclerosis and spinal cord–injured patients with DO also revealed an increased density of TRPV1 and $P2X_3$ immunoreactivity in suburothelial nerves, and increased TRPV1 immunoreactivity in the basal layer of the urothelium (Apostolidis et al., 2005b; Brady et al., 2004). Treatment of these patients with intravesical capsaicin or another C-fiber neurotoxin, RTX, reversed these abnormalities (Brady et al., 2004).

Insight into the mechanisms underlying the increased mechanosensitivity of C fibers after spinal cord injury has been gained by examination of the DRG cells innervating the bladder. Plasticity of these afferents manifests with enlargement of these DRG cells (Kruse et al., 1995) and increased electrical excitability (Yoshimura, 1999; Yoshimura and de Groat, 1997). Upregulation of tetrodotoxin (TTX)-sensitive Na^+ channels and downregulation of TTX-resistant Na^+ channels, as well as low-threshold A-type K^+ channels, occur after spinal cord injury (Yoshimura, 1999; Yoshimura and de Groat, 1997).

Plasticity in bladder afferents after spinal cord injury and upper motoneuron lesions may involve the retrograde transport of substances from either the spinal cord or the bladder to the DRG neuron. **NGF has been implicated as a chemical mediator of disease-induced changes in C-fiber afferent nerve excitability and reflex bladder activity** (Vizzard, 2000; Yoshimura, 1999). Chronic administration of NGF into bladder afferent pathways induced bladder overactivity and increased the firing frequency of dissociated bladder afferent neurons in rats (Vizzard, 2000; Yoshimura et al., 2006), and the production of neurotrophic factors, including NGF, increased in the bladder after spinal cord injury (Vizzard, 2000). Thus it seems that target organ–neural interactions mediated by neurotrophic factors, such as NGF, produced in the bladder may contribute to changes in C-fiber bladder afferent pathways that induce DO and detrusor-sphincter dyssynergia after spinal cord injury. In addition, increased NGF in the spinal cord after spinal cord injury is also responsible for inducing hyperexcitability of C-fiber bladder afferent pathways, and intrathecal application of NGF antibodies, which neutralizes NGF in the lumbosacral spinal cord and DRG, suppresses DO and detrusor-sphincter dyssynergia in spinal cord–injured rats (Seki et al., 2002). Intrathecal administration of NGF antibodies also blocks autonomic dysreflexia in paraplegic rats (Krenz et al., 1999). Thus NGF and its receptors in the bladder or the spinal cord are potential targets for new therapies to suppress DO and detrusor-sphincter dyssynergia after spinal cord injury.

Other neurogenic disorders associated with urgency incontinence respond to intravesical therapy with capsaicin or RTX, suggesting that plasticity in C-fiber afferents could form the neurogenic basis for DO (Fowler et al., 1994; Geirsson, 1993; Szallasi and Fowler, 2002). The emergence of a spinal reflex circuit activated by C-fiber bladder afferents represents a positive feedback mechanism (see Fig. 110.42) that may be unresponsive to voluntary control by higher brain centers and thereby be able to trigger involuntary voiding. **The bladder ice-water urodynamic test has been suggested as a method to assess the C-fiber–mediated micturition reflex.** Although the ice-water test is consistent in a strictly controlled research environment, it has not been adequately sensitive or specific in routine clinical use (Chai et al., 1998; Chancellor et al., 1998).

Neurogenic DO has also been associated with decreased expression and decreased activity of BK channels in the bladder smooth muscle (Hristov et al., 2013). BK channel activity (opening) underlies phase 2 and 3 hyperpolarization of the smooth muscle AP (see Fig. 110.16) and quells detrusor myocyte excitability. Therefore reduced expression and/or lessened function of the BK channels would necessarily lead to increased bladder contractions, hence DO. Although decreased BK expression and function in neurogenic DO help explain the mechanism behind neurogenic DO, the cause of decreased BK expression and function was not explored. This reference theorized that teleologically, decreased BK expression or function may be a consequence of a compensatory or adaptive mechanism in spinal cord injury patients that leads to increased detrusor smooth muscle contractility, allowing optimization of bladder emptying in the absence of normal innervation.

Key Points: Neurogenic Bladder

- Normal micturition is associated with a spinobulbospinal reflex mediated by lightly myelinated Aδ afferents.
- Unmyelinated C fibers are normally relatively insensitive to gradual distention of the urinary bladder.
- After spinal cord injury, a capsaicin-sensitive C-fiber–mediated spinal reflex develops and may play a role in the development of DO.
- Treatment of neurogenic DO patients with intravesical capsaicin or another C-fiber neurotoxin, RTX, produces symptomatic improvement in a subpopulation of these patients and reduces the density of TRPV1 immunoreactivity in nerve fibers and urothelium.
- The bladder ice-water urodynamic test has been suggested as a research method to assess the C-fiber–mediated micturition reflex but is not practiced clinically.

Nocturia

It is becoming recognized that nocturia, especially when occurring in isolation from other LUTS, represents a symptom with its own unique set of possible physiologic causes (Van Kerrebroeck and Andersson, 2014) including **global polyuria, nocturnal polyuria, reduced bladder capacity, sleep disorders, heart failure, and circadian clock disorders.** It has been shown that the **mouse bladder exhibits circadian rhythms in expression of Cx43** (Negoro et al.,

2012) and furthermore that Cx43 regulates bladder capacity in dark and light cycles of the mouse. During the light cycle, when the mouse is not active (equivalent to the human sleep cycle), Cx43 is downregulated, leading to increased bladder capacity (increased measure of volume voided per micturition). Conversely, during the dark cycle, when the mouse is awake and active, Cx43 is upregulated and bladder capacity is reduced (decreased volume voided per micturition). Transgenic animals with one of the circadian transcriptional regulators, Cry, knocked out developed loss of circadian oscillations of bladder capacity associated with loss of Cx43 expression oscillations. This study suggested that loss of the biologic clock mechanism in regulating Cx43 within the bladder may be a contributing mechanism to nocturia and nocturnal enuresis.

Bladder Outlet Obstruction

The bothersome symptoms of patients with urethral obstruction are in most cases caused by the bladder. BOO, such as that in patients with BPH, often produces detrusor hypertrophy and DO (Andersson and Wein, 2004; Gosling et al., 2000). After chronic partial obstruction of the urethra in rats, the bladder enlarges and is about 15 times heavier, but it has the same shape as in control rats; the growth is mainly accounted for by muscle hypertrophy. The outer surface of the hypertrophic bladder is increased sixfold over that of the controls; the muscle is increased threefold in thickness and is more compact. Mitoses are not found, but there is a massive increase in muscle cell size (Gabella and Uvelius, 1990). Obstruction-induced DO with irritative voiding symptoms has been attributed to denervation supersensitivity, because increased contractile responses of the bladder smooth muscle to cholinergic agonists have been observed (Andersson and Wein, 2004; Speakman et al., 1987). Alterations in detrusor contractility may also result from changes in contractile proteins (Chacko et al., 1999, 2004; Cher et al., 1990; Malmqvist et al., 1991). Changes in the contractile proteins occur in developing bladders and also during bladder hypertrophy (Sjuve et al., 1996; Wang et al., 1995; Wu et al., 1995). Obstructed bladders induced expression of SM-A (DiSanto et al., 2003). The obstructed bladder developed higher levels of force but with reduced cross-bridge cycling rates (Su et al., 2003). The ratio of SM1 to SM2 isoforms was also changed by BOO (Cher et al., 1996).

Brading and Turner (1994) proposed that all cases of DO have a common

feature—detrusor smooth muscle change that predisposes it to unstable contraction. They have demonstrated that DO, as shown in a pig model of obstruction, may occur without participation of a micturition reflex. Mills et al. (2000) have also implicated abnormalities in the detrusor muscle and its pattern of innervation in IDO. Compared with the bladder wall in control subjects, there was evidence in the detrusor smooth muscle of altered spontaneous contractile activity consistent with increased electrical coupling of cells, patchy denervation of the detrusor, and potassium supersensitivity (Mills et al., 2000). One of the manifestations of this abnormality is a partial denervation of the detrusor smooth muscle. In rats with BOO induced by partial urethral ligation, acetylcholine release during electric stimulation of obstructed bladder muscle strips was significantly decreased 3 to 6 months after obstruction, along with a reduction in the number of nerve fibers in the obstructed bladder compared with control rats (Murakami et al., 2008). Partial denervation in obstructed bladder leads to various functional changes in smooth muscles, including denervation supersensitivity of cholinergic (muscarinic) receptors (Speakman et al., 1987) and increases in purinergic receptor–mediated contractile responses as well as expression of purinergic receptors such as $P2X_1$ (Boselli et al., 2001; O'Reilly et al., 2001a). Changes in the cell-to-cell communication in detrusor muscles have also been indicated as a mechanism inducing DO, because there is an upregulation of Cx43, a gap-junction protein, in rats with DO induced by BOO (Christ et al., 2003; Imamura et al., 2009; Li et al., 2007; Mori et al., 2005). Increased expression of Cx43 is also identified in the bladders from patients with neurogenic DO (Haferkamp et al., 2004) or with urgency symptoms (Neuhaus et al., 2005). Thus increases in receptor-mediated muscle contractility and interaction among smooth muscle cells can result in coordinated myogenic contraction of the entire bladder and DO.

In addition, another population of cells in the bladder, known as *interstitial cells*, has been proposed to have a pacemaking role in spontaneous activity of the bladder (Andersson and Arner, 2004). **Because it has been reported that the number of interstitial cells is increased in a guinea pig model of BOO** (Kubota et al., 2008) **and that c-KIT tyrosine kinase inhibitors, which inhibit interstitial cell activity, decreased the amplitude of spontaneous contractions in the guinea pig and human bladder** (Biers et al., 2006; Kubota et al., 2006), **interstitial cells may also be involved in the emergence of DO as a result of enhanced autonomous detrusor muscle activity.**

Alterations also occur in neural networks in the CNS after obstruction of

the LUT. BOO in rats causes enhancement of a spinal reflex (Steers and De Groat, 1988). Similarly, in humans with obstruction, a capsaicin-sensitive spinal reflex can be detected by the ice-water test (Chai et al., 1998; Hirayama et al., 2003, 2005). Within the spinal cord, obstruction stimulates an increased expression of GAP43 that has been associated with axonal sprouting after injury (Steers et al., 1996). These observations suggest an enhancement or de novo development of new spinal circuits after obstruction. Similar to spinal cord injury, obstruction causes hypertrophy of bladder afferent and efferent neurons (Steers et al., 1990, 1991). A hypothesis proposed is that these newly formed spinal circuits (neuroplasticity), once formed, do not reverse easily even if obstruction is relieved because of persistent increased voiding frequency after relief of obstruction (Chai et al., 1999). An immunohistochemical analysis of the distribution and density of GAP43 showed that this protein was increased in the spinal cord in the region of the sacral parasympathetic nucleus in rats with BOO (Steers et al., 1996). Because this protein is a marker for axonal sprouting, its upregulation provides further indirect support for morphologic plasticity in afferent pathways after BOO. Nevertheless, these findings are not mutually exclusive of changes in the bladder smooth muscle, which are also likely to participate in the development of DO (Turner and Brading, 1997).

BOO appears to initiate the morphologic and electrophysiologic afferent plasticity through a mechanism involving NGF (see Fig. 110.42). NGF is responsible for the growth and maintenance of sympathetic and sensory neurons and has been shown to be responsible for neuronal regrowth after injury. NGF content is increased in obstructed bladders in animals and in humans (Steers et al., 1991). This increase in NGF content precedes the enlargement of bladder neurons and the developmental of urinary frequency (Steers et al., 1990, 1991). Moreover, blockade of NGF action with autoantibodies prevents the neural plasticity and urinary frequency after obstruction (Steers et al., 1996). In animals with persistent urinary frequency after relief of obstruction, NGF remains elevated in the bladder. These findings suggest a cause-and-effect relationship between NGF-mediated changes in bladder afferents and an enhanced spinal micturition reflex and urinary frequency associated with obstruction. Increased levels of urinary NGF have also been detected in BOO patients exhibiting OAB symptoms. Total urinary NGF levels were low in controls (0.5 pg/mL) and in patients with BOO without OAB symptoms (1 pg/mL), but considerably higher in patients with BOO and OAB symptoms (41 pg/mL) or BOO and DO (50 pg/mL). Investigators have examined urinary NGF before and after mid-urethral slings in females and found significantly increased NGF, corrected for creatinine, after mid-urethral slings (Chai et al., 2014), consistent with the finding that mid-urethral slings have a urodynamic cause of increased Pdet@Qmax (Kraus et al., 2011).

Key Points: Bladder Outlet Obstruction

- Obstruction-induced DO with irritative voiding symptoms has been attributed to denervation supersensitivity, because increased contractile responses of the bladder smooth muscle to cholinergic agonists have been observed. Alterations in detrusor contractility may also result from changes in contractile proteins.
- Increases in receptor-mediated muscle contractility and interaction among smooth muscle cells have been observed with BOO.
- BOO in rats causes enhancement of a spinal reflex.
- Bladder tissue and urine NGF content is increased in obstructed bladders in animals.

Underactive Bladder

Underactive bladder refers to LUTS suggesting diminished bladder contractility. Logically, these symptoms would be urinary emptying symptoms such as decreased force of stream, urinary hesitancy, interrupted stream, and straining to void. However, urinary storage symptoms such as urinary frequency, urgency, and nocturia often co-occur. Underactive bladder symptoms can also occur secondarily to bladder outlet obstruction, whether from prior suburethral sling in a female or BPH in a male. Therefore the symptoms of underactive bladder are nonspecific and furthermore do not denote a primary pathologic cause.

Decreased bladder contractility found during objective urodynamic testing is termed “detrusor underactivity.” The relationships between urodynamic finding of detrusor underactivity and lower urinary tract symptoms are not well understood. Although the concept of decreased detrusor contractility as the primary pathophysiology of detrusor underactivity seems appropriate, it is also important to consider that the afferent sensory mechanisms could be involved in detrusor underactivity. Decreased sensory input to the CNS may result in decreased detrusor contractility. Therefore detrusor underactivity may not just be due to pathophysiology of efferent mechanisms.

The utility of postvoid residual (PVR) volume determination in evaluation and management of patients who may have underactive bladder and/or detrusor underactivity is still not clear. An expert panel expert has made the recommendation of a PVR of at least 300 mL as the cutoff value before consideration of further evaluation (Stoffel et al., 2017). Furthermore, besides using this cutoff value, the presence of LUTS to moderately to severely affect quality of life or the presence of risk factors such as hydronephrosis, renal insufficiency, or urinary tract infections documented by positive cultures should prompt further evaluation and treatment. Also, a PVR of less than 300 mL does not imply that detrusor contractility is normal.

Bladder Pain Syndrome and Interstitial Cystitis

BPS/IC is a syndrome characterized primarily by pain attributable to the bladder associated with urinary frequency and urgency. This condition has no defined cause, although this section presents data from animal studies that offer some theoretical origins. **In Europe, the diagnosis of BPS/IC typically requires a bladder biopsy showing overt inflammation, so it is no surprise that histologic analysis of bladders from European patients with BPS/IC revealed marked edema, vasodilation, proliferation of nerve fibers, and infiltration of mast cells** (Johansson and Fall, 1997)**. However, the diagnosis of BPS/IC in the United States is driven primarily by symptoms of chronic bladder pain and urinary frequency and urgency in the absence of urinary tract infection (UTI).** In the United States, the diagnostic test, if performed, usually is hydrodistention of the bladder; and if a biopsy is performed, rarely is it a deep biopsy of the bladder stroma. The appearance of glomerulations (petechiae) after hydrodistention of the bladder as a diagnostic criterion for BPS/IC was first described by Messing and Stamey (1978), although the diagnostic specificity of glomerulations was questioned (Waxman et al., 1998). It appears that the diagnostic approach to BPS/IC varies between the United States and Europe.

Traditionally, BPS/IC is categorized as an inflammatory bladder disease, although the cause of the inflammation remains elusive (and some question whether BPS/IC is even an inflammatory disease). Cyclophosphamide-induced hemorrhagic cystitis has been used to model for BPS/IC, although there is no relationship between these two entities. Although the chemical cystitis model is important in understanding the neurobiologic response to inflammation, the relevance to BPS/IC remains to be validated in translational clinical trials.

Chemical cystitis resulted in sensitizing mechanosensitive afferents and/or recruitment of afferents normally unresponsive to mechanical stimulation (i.e., silent C fibers) (Dmitrieva and McMahon, 1996; Dmitrieva et al., 1997; Habler et al., 1990; Sengupta and Gebhart, 1994) and results in bladder inflammation. Proinflammatory agents, such as PGE_2, serotonin (5-HT), histamine, bradykinin, and adenosine, as well as neurotrophic factors such as NGF, which are released during chemical irritation, can induce bladder hyperactivity, as well as functional and chemical changes in C-fiber afferents that can lead to hyperexcitability (Dmitrieva and McMahon, 1996; Gold et al., 1996). For example, chronic chemical irritation of the bladder changes ion channel function in bladder afferent neurons and also increases the expression of various markers, including NOS (Vizzard et al., 1996), GAP43 (Vizzard and Boyle, 1999), PACAP, SP (Vizzard, 2001), and protease-activated receptors (Dattilio and Vizzard, 2005). The density of peptidergic afferent nerves also increases in the bladder mucosa and detrusor muscle (Dickson et al., 2006), and afferent peptidergic axons and parasympathetic efferent axons and varicosities are commonly observed in close contact, suggesting that sprouting of peripheral nerves occurs during chronic cystitis.

Cystitis also induces chemical changes in the spinal cord. Acute or chronic bladder irritation increases immediate early gene expression *(c-FOS)* in spinal neurons (Birder and de Groat, 1993), as well as increasing in GFRα1-IR in the spinal dorsal horn and in areas associated with autonomic neurons (Forrest and Keast, 2008). There was a much smaller increase in GFRα3-IR and no change in GFRα2-IR. Changes in spinal cord mitogen-activated protein (MAP) kinases (extracellular signal-related kinases 1 and 2 [ERK1 and ERK2]) may also play a role in the facilitation of reflex voiding after bladder inflammation. Immunohistochemical studies revealed that, in noninflamed rat bladders, noxious but not non-noxious stimulation significantly increased phospho-ERK immunoreactivity (Cruz et al., 2007). After bladder inflammation, innocuous and noxious bladder distention increased the number of spinal neurons exhibiting phospho-ERK immunoreactivity. ERK inhibition with intrathecal injection of PD98059 decreases reflex bladder activity and spinal c-FOS expression in animals with inflamed bladders but not in normal animals (Cruz et al., 2007). The results suggest that activation of spinal cord ERK contributes to acute and chronic inflammatory pain perception and mediates reflex bladder overactivity accompanying chronic bladder inflammation.

Direct evidence linking chronic bladder inflammation with functional changes in C-fiber afferents has been obtained in rat chronic cystitis models induced by cyclophosphamide or hydrochloric acid. In these models, the electrical properties of bladder afferent neurons (dissociated from L6 and S1 DRG), as well as the activity of the inflamed bladder, were measured. The majority of bladder afferent neurons from control and cyclophosphamide-treated rats are capsaicin sensitive and exhibit high-threshold TTX-resistant APs and Na^+ currents. However, neurons from rats with cystitis exhibit significantly lower thresholds for spike activation and show tonic rather than phasic firing characteristics (Hayashi et al., 2009b). Other significant changes in bladder afferent neurons from cystitis rats include increased somal diameter, increased input capacitance, and decreased density of slowly inactivating A-type K^+ (K_A) currents (Hayashi et al., 2009b; Yoshimura and de Groat, 1999). In addition, the reduction in K_A currents in the hydrochloric acid–induced cystitis model was associated with reduced expression of the Kv1.4 α-subunit protein (which can form K_A channels) in bladder afferent neurons (Hayashi et al., 2009b), suggesting that the Kv1.4 subunit may be a molecule responsible for reduced K_A currents and increased excitability of bladder afferent neurons after cystitis. Previous experiments using cats with naturally occurring feline-type IC have also demonstrated that capsaicin-sensitive dorsal root ganglion neurons exhibit an increase in cell size and increase in firing rates of depolarizing current pulses because of a reduction in low-threshold K^+ currents (Sculptoreanu et al., 2005). Accordingly, chronic inflammation in BPS/IC could induce cell hypertrophy and hyperexcitability of C-fiber bladder afferent neurons. If these changes in neuronal cell bodies also occur at C-fiber afferent terminals in the bladder wall, such hyperexcitability may represent an important mechanism for inducing pain in the inflamed bladder. This is supported by some clinical studies showing that C-fiber desensitization induced by intravesical application of capsaicin or RTX is effective for treating painful symptoms in patients with BPS/IC (Lazzeri et al., 1996, 2000), although a previous prospective, randomized clinical trial using intravesical RTX application was not effective in patients with BPS/IC (Payne et al., 2005).

There is little information available about the neuroplasticity of Aδ-fiber bladder afferents in BPS/IC. However, a previous study (Roppolo et al., 2005) using single nerve fiber recordings has documented that Aδ-fiber bladder afferents in cats with feline-type IC are more sensitive to bladder pressure changes than afferents in normal cats, suggesting that, in addition to neuroplasticity of C-fiber afferents, Aδ-fiber bladder afferents may also undergo functional changes in BPS/IC.

Chronic bladder inflammation can also induce changes in functional properties of chemosensitive receptors such as TRPV1 in sensory neurons. Sculptoreanu et al. (2005) reported that DRG neurons obtained from cats with feline IC exhibit capsaicin-induced responses that are larger in amplitude and desensitize more slowly compared with those obtained from normal cats, and that altered TRPV1 receptor activity in cats with feline IC is reversed by an application of an inhibitor of PKC, suggesting that BPS/IC can alter TRPV1 activity because of enhanced endogenous PKC activity. Because TRPV1 receptors are reportedly responsible, at least in part, for bladder overactivity elicited by cyclophosphamide-induced cystitis (Dinis et al., 2004), enhanced activity of TRPV1 receptors could contribute to bladder pain in BPS/IC. Studies in mice have also demonstrated a role of TRPV1 in cystitis. Systemic treatment with cyclophosphamide or intravesical administration of acrolein (the irritant metabolite of cyclophosphamide) produces not only bladder hyperactivity but also a sensitization of the paw withdrawal responses to mechanical stimulation of the paw (mechanical hyperalgesia). These responses do not occur in TRPV1 knockout mice (Charrua et al., 2007; Wang et al., 2008). In addition, GRC-6211, a new oral-specific TRPV1 antagonist, has been shown to decrease bladder overactivity and noxious bladder input in cystitis animal models (Charrua et al., 2009).

Afferent mechanisms can also explain the coexistence of pelvic organ hyperalgesia, such as BPS/IC and IBS. The animal model for this phenomenon is pelvic organ cross-sensitization. In this model, the rectum is exposed to a chemical irritant, with the resultant development of bladder afferent sensitivity, involvement of the C-fiber afferents, and bladder mast cell activation (Asfaw et al., 2011; Malykhina et al., 2013; Pan et al., 2010; Ustinova et al., 2006, 2010).

NGF has also attracted attention as a mediator in the link between experimentally induced inflammation and pain signaling in BPS/IC. NGF is expressed widely in various cells, including urothelial cells, smooth muscle cells, and mast cells, and can activate mast cells to degranulate and proliferate. In the cyclophosphamide-induced chronic cystitis model in rats, increased expression of neurotrophic growth factors, such as NGF, brain-derived neurotrophic factor (BDNF), and CNTF in the bladder, as well as phosphorylation of tyrosine kinase receptors (TrkA, TrkB) in bladder afferent neurons, has also been presented as direct evidence for increased neurotrophin-mediated signaling in chronic bladder inflammation (Qiao and Vizzard, 2002; Vizzard, 2000). The enhanced neurotrophic factor mechanisms are also associated with increased phosphorylated cAMP responsive element-binding protein (CREB) in bladder afferent neurons. Phosphorylated CREB, which is a transcription factor in the neurotrophin intracellular signaling pathway, is coexpressed with phosphorylated TrkA in a subpopulation of bladder afferent neurons (Qiao and Vizzard, 2004). RTX, a C-fiber neurotoxin, reduced cyclophosphamide-induced upregulation of phosphorylated CREB in DRG cells, suggesting that cystitis is linked with altered CREB phosphorylation in capsaicin-sensitive C-fiber bladder afferents (Qiao and Vizzard, 2004). These results suggest that upregulation of phosphorylated CREB may be mediated by a neurotrophin/TrkA signaling pathway, and that CREB phosphorylation may play a role as a transcription factor in LUT plasticity induced by chemical cystitis. In patients with BPS/IC, neurotrophins, including nerve growth factor, neurotrophin-3 (NT-3), and glial cell line–derived neurotrophic factor (GDNF), have been detected in the urine (Okragly et al., 1999). Increased expression of NGF is also present in bladder biopsy specimens from women with IC (Liu et al., 2014; Lowe et al., 1997).

Exogenous NGF can induce bladder nociceptive responses and bladder overactivity in rats when applied acutely into the bladder lumen (Chuang et al., 2001; Dmitrieva et al., 1997) or chronically to the bladder wall or intrathecal space (Lamb et al., 2004; Yoshimura et al., 2006; Zvara and Vizzard, 2007). Conversely, application of NGF-sequestering molecules (TrkA-IgG or REN1820) can reduce referred thermal hyperalgesia elicited by bladder inflammation induced by intravesically applied turpentine oil (Jaggar et al., 1999) or bladder overactivity elicited by cyclophosphamide-induced cystitis (Hu et al., 2005), suggesting that increased NGF expression is directly involved in the emergence of bladder-related nociceptive responses in cystitis. A urothelially restricted NGF expression transgenic animal has also been created (Schnegelsberg et al., 2010). This animal has increased voiding frequency and evidence of increased pelvic pain. The suburothelial nerve fibers also vastly expanded with hyperinnervation of the bladder with significantly increased mast cells in the bladder stroma, consistent with the trophic effects of NGF on this cell type. However despite these data, targeted treatment with monoclonal anti-NGF antibody, tanezumab, did not prove efficacious in BPS/IC patients (Evans et al., 2011). This may be a result of phenotyping issues in enrollment, and perhaps an entry criterion of threshold level of increased NGF would be required to show an effect. As discussed in a prior section, the use of NGF as a biomarker in evaluation and management of LUTD is still unresolved (Ochodnicky et al., 2011).

Purinergic mechanisms may also contribute to the bladder dysfunction in BPS/IC. ATP release from the urothelium is enhanced in patients and cats with BPS/IC (Birder et al., 2003; Sun et al., 2001). In conscious rats with cyclophosphamide-induced cystitis, purinergic receptor antagonists (pyridoxal-phosphate-6-azophenyl-2’,4’-disulfonic acid [PPADS] and A-317491) reduced nonvoiding contractions and decreased voiding frequency (Ito et al., 2008). In in vitro whole-bladder pelvic afferent nerve preparations from rats with cyclophosphamide-induced cystitis, afferent nerve firing induced by bladder distention or by direct electric stimulation was markedly increased compared with firing in normal rats (Yu and de Groat, 2008). Exogenous purinergic agonists mimic the facilitatory effects of cyclophosphamide treatment, and P2X purinergic receptor antagonists suppress the effects of purinergic agonists and cystitis. These results suggest that endogenous purinergic agonists released in the inflamed bladder can enhance the excitability of bladder afferent nerves by activating P2X receptors. Patch clamp studies on bladder afferent neurons from rats revealed that chronic cyclophosphamide treatment increases the currents induced by purinergic agonists in both thoracolumbar and lumbosacral neurons (Dang et al., 2008). Analysis of the kinetics of the currents indicated that increased receptor expression and/or properties of homomeric $P2X_3$ in thoracolumbar neurons and $P2X_{2/3}$ in lumbosacral neurons contributes to the enhanced responses during cystitis. Investigations with human BPS/IC bladder urothelial specimens found that stretch of cultured bladder urothelial cells resulted in significantly increased ATP release (Sun et al., 2001) and increased $P2X_3$ expression on the cells (Sun and Chai, 2004; Tempest et al., 2004). A $P2X_3$ antagonist, AF-219, has been tested in a proof-of-concept trial in treating symptoms associated with BPS/IC. In 36 and 38 BPS/IC women treated with AF-219 and placebo, respectively, patients treated with AF-219 had improvement in the key symptoms of BPS/IC: pain scores, urinary urgency, and general improvement in patient-reported symptoms, suggesting the potential efficacy of $P2X_3$ receptor antagonists for the treatment of BPS/IC symptoms

(Moldwin et al., 2015).

Another animal model for BPS/IC is chronic psychological stress inflicted by water avoidance stress (WAS) testing. In this model, a rat is placed on a narrow surface suspended over water. The rat becomes stressed because it must maintain balance to avoid getting wet. Changes in bladder neurophysiology then can be studied after chronic WAS. It was found that chronic WAS significantly enhanced visceral organ, including bladder, nociceptive responses (Bradesi et al., 2005; Robbins et al., 2007; Smith et al., 2011). Chronic WAS was noted to cause increased mast cell activity in the bladder, which was blocked with treatment with melatonin and montelukast (Cikler et al., 2005). Because stress mechanisms involve the brain, it could be theorized that the development of visceral hyperalgesia with chronic WAS involves brain mechanisms, which now can be imaged with fMRI in maintenance of the chronic pain state (Phillips and Clauw, 2011).

A search for urinary factors that may be a cause of BPS/IC resulted in discovery of antiproliferative factor (APF) by Keay et al. (1996, 1998). APF's structure was found to be a sialated glycol-nonapeptide with sequence homology to portion of the frizzled 8 protein of the Wnt signaling pathway (Keay et al., 2004). APF's receptor in the urothelial cell was found to be cytoskeletal-associated protein, CKAP4/p63 (Conrads et al., 2006). CKAP4/p63 is a palmitoylated protein that physically links the endoplasmic reticulum to the microtubules (Vedrenne et al., 2005). It is also a cell surface receptor for tissue plasminogen activator (Razzaq et al., 2003) and surfactant protein A (Gupta et al., 2006). CKAP4/p63 is a major substrate for a putative tumor suppressor enzyme, palmitoyl acyltransferase DHHC2 (Zhang et al., 2008), which may help explain APF's antiproliferative activity against urothelial cells. A mouse model in which intravesical application of APF resulted in similar bladder urothelial changes detected in human urothelium was published (Keay et al., 2012). Whether the understanding of APF biology can be integrated into care of BPS/IC patients remains to be seen.

Key Points: Bladder Pain Syndrome and Interstitial Cystitis

- Histologic analysis of bladders from patients with BPS/IC often revealed marked edema, vasodilation, proliferation of nerve fibers, and infiltration of mast cells.

- NGF appears to be a key player in the link between inflammation and altered pain signaling. NGF is expressed widely in various cells, including urothelial cells, smooth muscle cells, and mast cells, and can activate mast cells to degranulate and proliferate.
- Application of NGF-sequestering molecules can reduce bladder overactivity elicited by cyclophosphamide-induced cystitis.
- Direct evidence linking chronic bladder inflammation with functional changes in C-fiber afferents has been obtained in rat chronic cystitis models. Chronic bladder inflammation can also induce changes in functional properties of chemosensitive receptors, such as TRPV1 in sensory neurons.

Aging

LUTS, such as increased voiding frequency, urgency, urgency incontinence, and poor bladder emptying, are common and troublesome problems in older men and women (Naughton and Wyman, 1997; Nuotio et al., 2002; Resnick, 1995). Previous studies have reported various changes in LUT function, including a reduction in bladder capacity, increased bladder sensation, and DO (Diokno et al., 1986; Hald and Horn, 1998; Madersbacher et al., 1998, 1999; Nuotio et al., 2002). However, few studies have addressed the normal changes in the LUT that occur with aging. Studies by Pfisterer et al. (2006) have examined age-related changes in bladder function among 85 community-dwelling female volunteers and **demonstrated that detrusor contractility, bladder sensation, and urethral pressure decline with age** and that a reduction in bladder capacity associated with age may be related to DO rather than to aging, because bladder capacity did not decrease with age but was smaller in subjects with DO (Pfisterer et al., 2006). With aging, pelvic ischemia can occur as a result of vasculopathy, which can result in LUTS and detrusor overactivity (Azadzoi et al., 2010; Thurmond et al., 2016). Thus **aging appears to induce hypofunction of the bladder and urethra in humans.**

Epidemiologic studies have revealed that aging is the largest risk factor for lifestyle-related diseases or disorders, including bladder conditions; however, the underlying mechanisms that underlie the increased risk remain unclear. There is substantive evidence that cellular senescence and increased oxidative stress can contribute to changes in tissue perfusion, leading to a reduction in tactile and visceral hyposensitivity as well as abnormal urodynamic behavior in older adults. A report highlights how the TAME trial (Targeting Aging with Metformin) may help decrease age-related disease by targeting fundamental aging pathways including oxidative stress. Although metformin was originally introduced in clinical practice as an agent to treat diabetes, its use is being expanded to promote longevity and has been shown in mice to increase lifespan. Long-term caloric restriction may have effects on similar pathways and has also been shown to prevent age-related impairment of in vitro bladder dysfunction (Barzilai et al., 2016; Dai et al., 2014; Ito et al., 2015; Martin-Montalvo et al., 2013).

In animal studies, impaired bladder function, as evidenced by increased voided volume per micturition associated with a high micturition-pressure threshold, has also been demonstrated in aged rats compared with the young counterpart (Chai et al., 2000; Chun et al., 1988). In addition, aged rats exhibit reduced sensitivity of pelvic nerve afferents in response to increased bladder volume, but not pressure, and a reduction in the maximal bladder pressure generated during pelvic nerve stimulation (Hotta et al., 1995). In aging mice, bladder contractility was normal, but bladder afferent signaling was diminished (Smith et al., 2012a).

A significant linear reduction in the amount of acetylcholinesterase-positive nerve was observed with increasing age in the human bladder (Gilpin et al., 1986), suggesting reduced parasympathetic innervation of the aged bladder. It was also shown that expression of neuropeptides, such as CGRP and SP in lumbosacral DRG neurons, decreases with age (Mohammed and Santer, 2002) and that there is a marked reduction in the density of PACAP innervation of the subepithelial plexus and of the muscle layer of the bladder base, as well as slight reductions in CGRP and SP innervation of the muscle layer in old rats (Mohammed and Santer, 2002; Mohammed et al., 2002). Taken together, these results suggest that **impaired activity of the aged bladder is likely, at least in part, a result of reduced activity of efferent and afferent nerves innervating the bladder.**

Changes in the CNS in relation to LUT function have also been demonstrated in aged animals. Immunohistochemical analyses in aged rats revealed significant age-associated declines in the serotonergic (5-HT) and adrenergic innervation of various spinal cord regions, including the intermediolateral cell nucleus, sacral parasympathetic nucleus, dorsal gray commissure, and the ventral horn nucleus that contains the Onuf nucleus. However, 5-HT innervation of the sacral parasympathetic nucleus and tyrosine hydroxylase–like immunoreactivity in the ventral horn nucleus were maintained (Ranson et al., 2003). It was also shown that sympathetic preganglionic neurons in the L1-L2 spinal cord that project to the major pelvic ganglion exhibit a number of degenerative changes, such as reductions in the cell number, the length of their dendrites, and the synaptic contact made by glutamate-immunoreactive boutons onto the dendrites in aged rats, although these changes are not seen in parasympathetic preganglionic neurons in the L6-S1 spinal cord (Santer et al., 2002). Chai et al. (2000) also reported that frequent voiding produced by apomorphine-induced dopamine receptor activation is more pronounced in aged rats compared with young rats, suggesting that aged rats are more susceptible to altered central processing to induce bladder overactivity despite decline of baseline bladder function with aging. Hypoactivity of the bladder or the underactive bladder represents an unmet medical need moving forward in light of the aging populations in developed countries (Chancellor and Kaufman, 2008).

In contrast to altered nerve activity, there appears to be no significant change in detrusor contractile responses to cholinergic or electric stimulation between young and old animals (Chun et al., 1989; Lieu et al., 1997; Lin et al., 1997; Longhurst et al., 1992; Schneider et al., 2004b; Yu et al., 1996), although old rats have a reduced density of muscarinic receptors in the bladder (Schneider et al., 2004b). In contrast, there are some reports of age-related changes of the detrusor response to adrenergic stimulation (Latifpour et al., 1990). Most studies showed that detrusor contractile responses to α-adrenergic stimulation increased in old male and female rats (Lin et al., 1997; Nishimoto et al., 1995; Saito et al., 1991, 1993) in association with upregulation of α_{1D}-receptor expression in the bladder (Dmitrieva et al., 2008). However, another study showed no age-dependent changes in α_1-adrenoceptor properties, such as phenylephrine-induced contractile responses, total receptor density, and mRNA expression of α_1-adrenoceptor subtypes (α_{1A}, α_{1B}, and α_{1D}) in the rat bladder base and dome (Yono et al., 2006). The detrusor response to β-adrenergic stimulation is reduced in old male rats (Lin et al., 1997; Nishimoto et al., 1995), along with a reduction in the density of β-adrenergic receptors and decreased cAMP production (Nishimoto et al., 1995) in response to β-adrenergic stimulation. The combination of increased α-adrenergic excitatory response and decreased β-adrenergic inhibitory response results in a net contracting effect of norepinephrine on the aged bladder, in contrast to the relaxing effect of norepinephrine in the young bladder (Lin et al., 1997). However, the contribution of these changes in adrenoceptor properties to age-related alterations in LUT function is still to be determined.

Pharmacologic treatment of LUTS in the elderly often involves the use of antimuscarinic agents. The urologic use of antimuscarinics can increase risk of cognitive function decline (see the earlier section on cognitive impairment with antimuscarinic agents), especially because the elderly may be on several other medications with anticholinergic activity (increased anticholinergic burden). A case control study of approximately 40,000 cases (dementia) and 280,000 controls without dementia found that the risk for dementia increased with greater exposure to anticholinergics (oxybutynin and tolterodine) used for urologic indications (Richardson et al., 2018). However, it could not be determined from this study whether the increased dementia risk was increased because of anticholinergic side effects of oxybutynin/tolterodine or whether urologic symptoms being treated were prodromal for development for dementia.

Key Points: Aging

- Bladder sensation and urethral pressure decline with age, and a reduction in bladder capacity associated with age may be related to DO rather than to aging, because bladder capacity was not seen to decrease with age but was smaller in subjects with DO. Thus aging appears to induce hypofunction of the bladder and urethra in humans.
- In contrast to altered nerve activity, there appears to be no significant change in detrusor contractile responses to cholinergic or electric stimulation between young and old animals.
- Most studies have shown that detrusor contractile responses to α-adrenergic stimulation increase and that detrusor-relaxing responses to β-adrenergic stimulation decrease in old rats.

Neuromodulation

Hypothesis of Mechanism of Action of Sacral Neuromodulation

Neuromodulation of the sacral, pudendal, and posterior tibial nerves is now used for the treatment of refractory OAB and urinary retention relating to pelvic floor dysfunction (Das et al., 2004; Herbison and Arnold, 2009; Leng and Chancellor, 2005). Some have criticized the inconsistency that electric stimulation of the sacral nerve can paradoxically inhibit the OAB and conversely promote bladder emptying in patients with idiopathic nonobstructive urinary retention. The effects of sacral neuromodulation may depend on electric stimulation of afferent axons in the spinal roots, which in turn modulate voiding and continence reflex pathways in the CNS. The afferent system is the most likely target, because beneficial effects can be elicited at intensities of stimulation that do not activate movements of striated muscles (de Groat et al., 1997; Thon et al., 1991; Vodusek et al., 1986). Sacral neuromodulation activates somatic afferent axons that modulate sensory processing and micturition reflex pathways in the spinal cord. Urinary retention and dysfunctional voiding can be resolved by inhibition of the guarding reflexes. DO can be suppressed by direct inhibition of bladder preganglionic neurons. Inhibition of interneuronal transmission in the afferent limb of the micturition reflex can also block DO. Thus the principle behind sacral neuromodulation can be summarized as somatic afferent inhibition of sensory processing in the spinal cord.

Rationale for Neuromodulation to Facilitate Voiding

In adults, brain pathways are necessary to turn off sphincter and urethral guarding reflexes to allow efficient bladder emptying. Thus spinal cord injury produces bladder-sphincter dyssynergia and inefficient bladder emptying by eliminating the brain mechanisms involved (Fig. 110.43). This may also occur after more subtle neurologic lesions in patients with idiopathic urinary retention, such as after a bout of prostatitis or UTI. Before the development of brain control of micturition, at least in animals, the stimulation of somatic afferent pathways passing through the pudendal nerve from the perineum can initiate efficient voiding by activating bladder efferent pathways and turning off the excitatory pathways to the urethral outlet (de Groat and Booth, 1993; de Groat et al., 1993; Kruse and de Groat, 1993). Tactile stimulation of the perineum in the cat also inhibits the bladder–sympathetic reflex component of the guarding reflex mechanism. The sacral nerve stimulation may elicit similar responses in patients with urinary retention, and it may turn off excitatory outflow to the urethral outlet and promote bladder emptying. Because sphincter activity can generate afferent input to the spinal cord that can, in turn, inhibit reflex bladder activity, an indirect benefit of suppressing sphincter reflexes would be a facilitation of bladder activity.

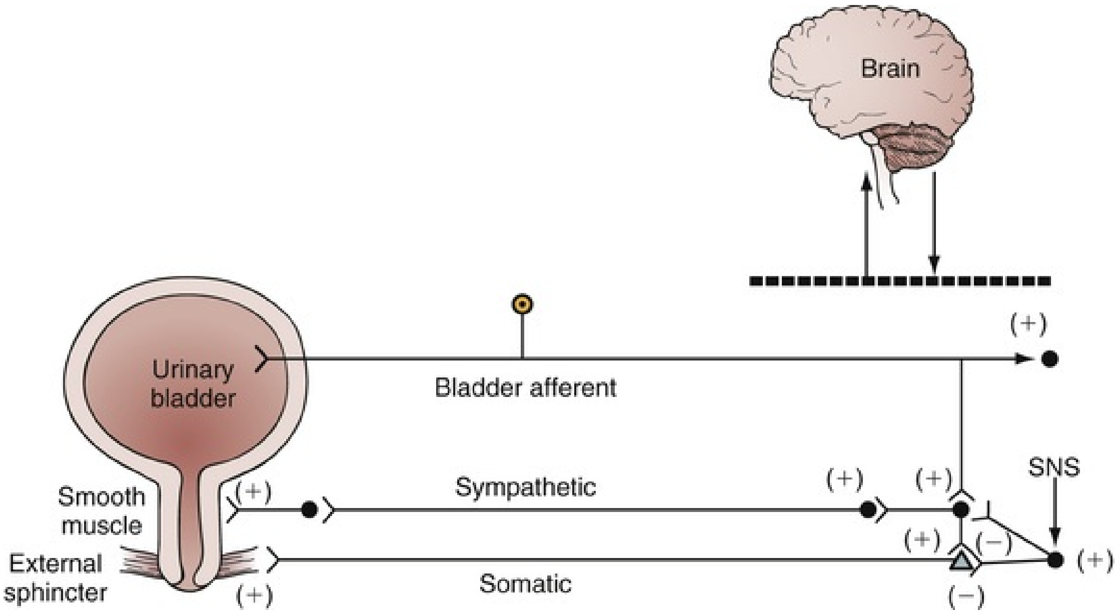

FIG. 110.43 When there is a sudden increase in intravesical pressure, such as during a cough, the urinary sphincter contracts by means of the spinal guarding reflex to prevent urinary incontinence (guarding reflex). The spinal guarding reflexes can be turned off by the brain for urination. In cases of neurologic diseases, the brain cannot turn off the guarding reflex, and retention can occur. Sacral nerve stimulation (SNS) restores voluntary micturition in cases of voiding dysfunction and urinary retention but inhibits the guarding reflex.

Rationale for Neuromodulation to Inhibit the Overactive Bladder

Several reflex mechanisms may be involved in the sacral neuromodulation suppression of DO. Afferent pathways projecting to the sacral cord can inhibit bladder reflexes in animals and humans. The source of afferent input may be from sphincter muscles, distal colon, rectum, anal canal, vagina, uterine cervix, and cutaneous afferents from the perineum (Fig. 110.44). As mentioned previously, two mechanisms have been identified in animals for somatic and visceral afferent inhibition of bladder reflexes. The most common mechanism is suppression of interneuronal transmission in the bladder reflex pathway (de Groat and Theobald, 1976; Kruse and de Groat, 1993; Kruse et al., 1990). It is assumed that this inhibition occurs, in part, on the ascending limb of the micturition reflex and therefore blocks the transfer of information from the bladder to the PMC. This action would prevent involuntary (reflex) micturition but not necessarily suppress voluntary voiding that would be mediated by descending excitatory efferent pathways from the brain to the sacral parasympathetic preganglionic neurons. A second inhibitory mechanism is mediated by a direct inhibitory input to the bladder preganglionic neurons. This can be induced by electric stimulation of the pudendal nerve or by mechanical stimulation of the anal canal and distal bowel. It is not elicited by tactile stimulation of penile or perineal afferents; this mechanism would be much more effective in turning off bladder reflexes, because it would directly suppress firing in the motor outflow from the spinal cord.

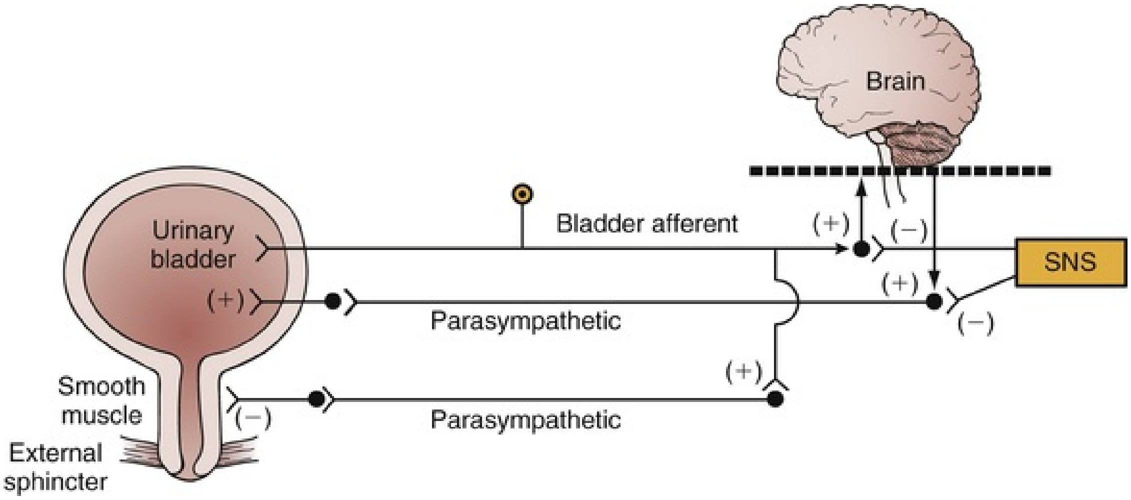

FIG. 110.44 The voiding reflex involves afferent neurons from the bladder that project on spinal tract neurons that ascend to the brain. Descending pathways connect to parasympathetic efferent nerves to contract the bladder (bladder-bladder reflex). A spinal bladder-urethra reflex is activated by a similar bladder afferent innervation. In cases of supraspinal dysfunction, overactive micturition reflexes occur. Sacral nerve stimulation (SNS) inhibits urinary urgency, frequency, and urge incontinence by inhibiting the bladder-bladder and bladder-urethra reflexes.

Pudendal Nerve Stimulation

The pudendal nerve is a peripheral branch of the sacral nerve roots, and stimulating the pudendal allows afferent stimulation to all three of the sacral nerve roots (S2, S3, S4), and that may raise the stimulation threshold needed for micturition and inhibit detrusor activity. Because this is a more peripheral nerve, it is less likely that stimulation of the sciatic and sural nerves will occur, thus decreasing the potential risk for discomfort in the thighs, calves, and feet as seen on occasion with sacral stimulation at the S3 nerve root. The pudendal nerve arises from the sacral plexus within the pelvis; it must go around the pelvic floor to reach the ischioanal fossa. In the pelvis, it runs on the piriformis and then passes laterally through the greater sciatic foramen to enter the gluteal region. Here it lies inferior to the piriformis as does the sciatic nerve, the inferior gluteal neurovascular bundle, and the nerve to the quadratus femoris. The pudendal nerve curls around the spine of the ischium, lying superficial to the sacrospinous ligament, and then passes into the lesser sciatic notch to enter the ischioanal fossa. The nerve then divides into the inferior rectal, the perineal, and the dorsal nerve of the penis or clitoris.

Afferent pudendal nerve stimulation has been demonstrated to inhibit the micturition reflex, abolish uninhibited detrusor contractions, and increase bladder capacity in animals and humans (Fall and Lindstrom, 1991). Peters et al. (2005) compared the effectiveness of sacral and pudendal nerve stimulation for voiding dysfunction in a prospective, single-blind, randomized crossover trial including 30 patients (22 with urgency or frequency, 5 with urgency incontinence, and 3 with urinary retention) scheduled for sacral implantation of a tined quadripolar lead who consented to the placement of a second pudendal lead. Twenty-four of the 30 patients demonstrated a significant clinical response and had an implantable pulse generator placed. Sacral nerve stimulation resulted in 46% improvement in symptoms, whereas pudendal nerve stimulation demonstrated 63% improvement in symptoms. Urgency-incontinence episodes were reduced by approximately 47%; however, this did not reach statistical significance because of small sample size (n = 5).

Inhibitory and Excitatory Stimulation Frequencies of the Pudendal-Bladder Reflexes

The exact mechanism of action of neuromodulation is unknown. In addition, there are no studies involving neuromodulation that look at programming parameters (pulse width, intensity, or frequency) and their impact on voiding function. The pudendal nerve may have a dual mechanism depending on the frequency and continuity of stimulation. A study by Tai et al. (2007) in anesthetized spinal cord–injured cats demonstrated that at 3 Hz, stimulation of the pudendal nerve inhibited bladder function and decreased bladder pressures, whereas intermittent stimulation at 20 Hz improved the efficiency of the bladder to empty (Tai et al., 2007). Furthermore, the clinical outcomes of continuous (which potentially can fatigue the urethral sphincter and accommodate the nerve) and intermittent stimulation have not been explored. It would directly suppress firing in the motor outflow from the spinal cord.

Activation of Somatic Afferents in the Foot

There is also evidence that using noninvasive transcutaneous stimulation of somatic nerves in the footpad of cats produced an inhibition of reflex bladder activity (Tai et al., 2011a,b). In this regard, a new treatment termed FootStim has been used as a noninvasive foot neuromodulation therapy for OAB. Using a wearable stimulator, the patient is able to use the device at home to activate nerves on the foot via skin surface electrodes. Results using FootStim (3 hours daily) showed decrease urgency urinary incontinence and urgency frequency in women with refractory OAB (Chermansky et al., 2017).

OnabotulinumtoxinA Neuromodulation

Botulinum toxins act by inhibiting ACh release at the presynaptic cholinergic nerve terminal, thereby inhibiting striated and smooth muscle contractions. The toxins are synthesized as single-chain polypeptides with a molecular weight of about 150 kD (DasGupta, 1994). Initially, the parent chain is cleaved into its active dichain polypeptide form, consisting of a heavy chain (approximately 100 kD) connected by a disulfide bond to a light chain (approximately 50 kD) with an associated zinc atom (Schiavo et al., 1992). Four steps are required for toxin-induced paralysis: binding of the toxin heavy chain to an as yet unidentified nerve terminal receptor, internalization of the toxin within the nerve terminal, translocation of the light chain into the cytosol, and inhibition of neurotransmitter release. Neurotransmitter release involves the ATP-dependent transport of the vesicle from the cytosol to the plasma membrane (Barinaga, 1993). Vesicle docking requires the interaction of various cytoplasm, vesicle, and target membrane proteins (i.e., soluble *N*-ethylmaleimide-sensitive factor attachment protein receptor [SNARE] proteins), some of which are specifically targeted with clostridial neurotoxins. For example, OBTX cleaves the cytosolic translocation protein SNAP-25, thus preventing vesicle fusion with the plasma membrane (Schiavo et al., 1993).

Although ACh release from bladder parasympathetic efferent terminals is a likely target of OBTX treatment, suppression of bladder afferent activity with

OBTX treatment is also evident because the reduction of urgency symptom in patients with neurogenic detrusor overactivity and IDO is associated with reduced expression of the capsaicin receptor (TRPV1) and the ATP receptor ($P2X_3$) in C fibers (Apostolidis et al., 2005a). In addition, in basic research, botulinum toxins are shown to suppress not only efferent nerve activity by inhibition of the release of ACh but also afferent nerve activity by release of inhibition of neurotransmitters, such as SP and CGRP, from sensory terminals (Chuang et al., 2004; Dressler et al., 2005; Ikeda et al., 2012). There is also evidence that the toxin can reduce the release of ATP (and possibly other mediators) from urothelial cells in control urothelial cells (Hanna-Mitchell et al., 2015) and in spinalized rats (Khera et al., 2004; Smith et al., 2005, 2008). A study using lipotoxin (liposomes as a carrier for OBTX) demonstrated that the urothelium is also a site of action for this treatment (Kuo et al., 2014). Thus the use of the toxins has been expanded to treat women with pelvic floor spasticity, as well as patients with non-neurogenic OAB and even BPS (Apostolidis and Fowler, 2008; Smith and Chancellor, 2004; Smith et al., 2003, 2005).

The use of intradetrusor OBTX injection versus oral antimuscarinics in idiopathic OAB with urgency incontinence was studied in a randomized comparative efficacy trial (Visco et al., 2012). Reduction in urgency incontinence episodes per day was not different between OBTX and antimuscarinics, but the rate of complete resolution of urgency incontinence was significantly higher in the OBTX-treated subjects. The antimuscarinic-treated subjects had a higher rate of dry mouth but lower rates of catheter use and UTI.

A randomized clinical trial comparing OBTX injection with sacral neuromodulation was conducted in women with refractory idiopathic, non-neurogenic, overactive bladder with 24-month follow-up data (Amundsen et al., 2016, 2018). These investigators found that the efficacy of the two treatments were comparable with higher complete dry rate with OBTX, although the OBTX dosage used was 200 units. There was higher UTI risk with OBTX injection.

Future Research

Research holds the key to advancing the evaluation, treatment, and prevention of LUTD. As research delves deeper into physiology and pharmacology of the lower urinary tract, it is vital to continually translate research findings into clinical advances. A continuing dialogue between the clinician and scientist must be maintained. Newer treatments such as OBTX, β_3-agonists, sacral neuromodulation, and posterior tibial neurostimulation have been implemented into our armamentarium, but what is next on the horizon? Although traditional physiologic, pharmacologic, and neurobiologic approaches will continue to be important, the field of LUTD will require innovations that have advanced other fields.

High throughput screening "omics" techniques—genomics, proteomics, transcriptomics, lipidomics, and metabolomics have been used in many other diseases and conditions. These "omics" techniques use evolving technologies to analyze the entire genome, every protein, every mRNA, every lipid, and/or every metabolite within a biologic specimen to find signature abnormalities that could point to biologic causes for the conditions being studied. Through the use of "omics" techniques, we will be able to describe a "deeper" phenotyping of patients with LUTD, moving beyond symptoms-based phenotyping. Phenotyping based on large sets of biologic markers may help prognosticate outcomes of LUTD treatment, identify causes for LUTD, and/or point to new biologic pathways involved in LUTD.

Pharmacogenomics is a field that seeks to identify individual genetic variations that influence drug effects (typically via alterations in pharmacokinetics). Knowing which genetic variations are associated with increased (or decreased) efficacy of a drug, coupled with genotyping of patients, would lead to individualized pharmacologic therapeutic approaches.

Tissue regeneration and stem cell research has undergone significant progress over the last decade and reviews relating this area of research to the lower urinary tract have been published (Chan et al., 2017). New methodologies, including advancement in material science, stem cell technology, and methods to promote antiogenesis and neural regeneration, have yielded possibilities that may translate into LUT applications, including ways to augment bladder storage and emptying and urethral closure function. Using stem cells (e.g. mesenchymal stem cells) to promote salutary mechanisms after injuries may prevent future organ dysfunction or accelerate process towards healthy organ function.

Continued studies into different forms of functional neuromodulation in treating the myriad of LUTD conditions appear warranted as the understanding of brain control of lower urinary tract function is better understood. Although stimulating a nerve root (S3) or peripheral nerve (posterior tibial nerve, foot nerve, saphenous nerve) (MacDiarmid et al., 2018) to modulate LUT function has been described, the future of brain stimulation to treat LUTD remains an area of research interest. With better understanding of the brain involvement in regulating lower urinary tract function through functional MRI techniques, future treatments to modulate the function and network connectivity of these brain areas using stimuli such as transcranial magnetic stimulation (TMS) require further research. TMS has already been applied to a wide variety of mental health and behavioral disorders such as depression (McClintock et al., 2018), schizophrenia (Aleman et al., 2018), addiction (Diana et al., 2017; Spagnolo and Goldman, 2017), and nonessential tremor (Kang and Cauraugh, 2017).

Investigations into the urinary microbiota are ongoing. Researchers have categorized the genera of bacteria that dwell are found in the urine from normal individuals (Wolfe et al., 2012) and subjects with overactive bladder/urgency urinary incontinence (Brubaker et al., 2014; Pearce et al., 2014) and IC/PBS (Nickel et al., 2016; Siddiqui et al., 2012). Although this chapter does not cover microbiome/bacterial biology, the urothelium, lamina propria, and afferent/efferent neural pathways are host biologic systems by which interactions occur with the urinary microbiota. Thus a more granular understanding of the role of urinary microbiota in LUTD symptoms would necessarily require an understanding of host responses to the urinary microbiota.

Questions for future research may include the following:

1. Can we prevent development of any form of LUTD based on our understanding of pathophysiologic mechanisms?
2. Will stratifying patients into treatment groups based on genotype lead to development of “personalized” pharmacotherapy?
3. Can we develop biomarkers to better phenotype different forms of LUTD?
4. Can the biomarkers be used to prognosticate treatment outcomes?
5. Can the biomarker search result in novel targets for treatment?

6. Can genomics studies point to susceptibility genes for the development of LUTD?
7. Can the afferent signals from the LUT be modulated to treat a variety of LUTD?
8. Is the bladder urothelium targetable to treat different forms of LUTD?
9. Will a pharmacologic or physiologic intervention be developed that will successfully treat the underactive detrusor so that self-catheterization is obsolete?
10. Will regenerative medicine technologies be shown to be clinically useful in LUTD?
11. How does the host respond to urinary microbiota in the normal and LUTD states?

Pathophysiology and Classification of Lower Urinary Tract Dysfunction

Overview

Elizabeth Timbrook Brown MD, MPH, Alan J. Wein MD, PhD (Hon), FACS, Roger R. Dmochowski MD, MMHC, FACS

The lower urinary tract (LUT) functions as a group of interrelated structures whose joint function in an adult is to bring about efficient and low-pressure bladder filling, low-pressure urine storage with perfect continence, and periodic complete voluntary urine expulsion also at low pressure. Appropriate sensation should accompany the function of the LUT, meaning that a sense of deferrable bladder fullness should gradually occur between voluntary voids up to a volume that is sufficient to prevent urinary frequency and without any pain or sudden compelling desires to void that are difficult to defer (urgency). Because the LUT in adults is normally under voluntary neural control, it is clearly different from other visceral organs innervated by the autonomic nervous system, whose regulation is solely by involuntary mechanisms.

For the purposes of description and teaching, the micturition cycle is best divided into two relatively discrete phases: bladder filling/urine storage and bladder emptying/voiding. The micturition cycle normally displays these two modes of operation in a simple on-off fashion. The cycle involves switching from inhibition of the voiding reflex and activation of the storage reflexes to inhibition of the storage reflexes and activation of the voiding reflex and back again. This chapter begins with a functional, physiologic, and pharmacologic overview of normal and abnormal LUT function. A simple way of looking at the pathophysiology of all types of voiding dysfunction is then presented, followed by a discussion of various systems of classification and categorization.

Consistent with prior attempts to make the understanding, evaluation, and management of voiding dysfunction as logical and simple as possible (Wein, 1981, 2002; Wein and Barrett, 1988), a functional and practical approach is favored.

Normal Lower Urinary Tract Function: Overview

Two-Phase Concept of Function: Filling/Storage and Emptying/Voiding

Whatever disagreements exist regarding the anatomic, morphologic, physiologic, pharmacologic, and mechanical details involved in the storage and the expulsion of urine by the LUT, "experts" would agree on several general points and guiding principles (Wein, 1981, 2007; Wein and Barrett, 1988; Wein and Moy, 2007). The first is that **the micturition cycle involves two relatively discrete processes: (1) bladder filling and urine storage and (2) bladder emptying or voiding.** The second is that, whatever the details involved, **one can succinctly summarize these processes from a conceptual point of view as follows:**

Bladder filling and urine storage require the following:

- Accommodation of increasing volumes of urine at a low detrusor pressure (normal compliance) and with appropriate sensation
- A bladder outlet that is closed at rest and remains so during increases in intra-abdominal pressure
- Absence of involuntary bladder contractions (detrusor overactivity [DO])

Bladder emptying and voiding require the following:

- A coordinated contraction of the bladder smooth musculature of adequate magnitude and duration
- A concomitant lowering of resistance at the level of the smooth and striated sphincter (no functional obstruction)
- Absence of anatomic (as opposed to functional) obstruction

The **smooth sphincter** refers to the smooth musculature of the bladder neck and proximal urethra. This is a physiologic but not an anatomic sphincter and one that is not under voluntary control. The **striated sphincter** refers to the striated musculature that is a part of the outer wall of the proximal urethra in males and females (this portion is often referred to as the **intrinsic or intramural striated sphincter or rhabdosphincter**). The **striated sphincter** also refers to the bulky skeletal muscle group that closely surrounds the urethra at the level of the membranous portion in males and primarily the middle segment in females (often referred to as the **extrinsic or extramural striated sphincter**). The extramural portion is the classically described **external urethral sphincter** and is under voluntary control (for a detailed discussion see Chapter 110) (Birder et al., 2013; Brading et al., 2001; DeLancey et al., 2002; Zderic et al., 2002).

Mechanisms Underlying the Two Phases of Function: Overview

This section briefly summarizes pertinent points regarding the physiology and pharmacology of the various mechanisms underlying normal bladder filling/storage and emptying/voiding that constitute the pathophysiologic mechanisms seen in the various types of dysfunction of the LUT. The general information is consistent with that detailed in Chapter 110 and in previous source materials and their supporting references (Andersson, 2014; Andersson and Arner, 2004; Andersson and Wein, 2004; Beckel and Holstege, 2011; Birder et al., 2013; de Groat, 2006; de Groat et al., 1993, 1999; de Groat and Yoshimura, 2001; Fowler et al., 2008; Koelbl et al., 2013; Michel and Barendrecht, 2008; Morrison et al., 2005; Mostwin et al., 2005; Ochodnicky et al., 2013; Wein and Barrett, 1988; Yoshimura and Chancellor, 2007; Zderic et al., 2002). Other specific references are provided only when particularly unique or applicable.

Bladder Response During Filling

The normal adult bladder response to filling at a physiologic rate is an almost imperceptible change in intravesical and detrusor pressure. During at least the initial stages of bladder filling, after unfolding of the bladder wall from its collapsed state, this high compliance (Δ volume/Δ pressure) of the bladder is due primarily to its elastic and viscoelastic properties. Elasticity allows the constituents of the bladder wall to stretch to a certain degree without any increase in tension. Viscoelasticity allows stretch to induce an increase in tension followed by a delay (“stress relaxation”) when the filling (stretch stimulus) slows or stops. The viscoelastic properties are considered to be primarily due to the characteristics of the extracellular matrix in the bladder wall. Andersson and Arner (2004) cite references demonstrating that the main extracellular components are elastic fibers and collagen fibrils present in the serosa, between muscle bundles, and between the smooth muscle cells in the muscle bundles. Brading et al. (1999) state that they believe there is continuous contractile activity in the smooth muscle cells to adjust their length during filling but without the type of synchronous activity that would increase intravesical pressure, would impede filling, and could cause urinary leakage. Neal et al. (2017) believe that intrinsic bladder compliance regulation is also dependent on the regulation of actomyosin cross-bridge activity. Clinically and urodynamically, the bladder seems “relaxed.” The urothelium also expands but must preserve its barrier function while doing so.

There may also be a non-neurogenic active component to the storage properties of the bladder. Hawthorn et al. (2000) have suggested that an as yet unidentifiable relaxing factor is released from the urothelium during filling and storage, and Andersson and Wein (2004) and Andersson (2014) have suggested that urothelium-released nitric oxide may have an inhibitory effect on afferent mechanisms as well.

The viscoelastic properties of the stroma (bladder wall less smooth muscle and epithelium) and the urodynamically noncontractile state of the detrusor muscle account for the passive mechanical properties and normal bladder compliance seen during filling. The main components of the stroma are collagen and elastin. In the usual clinical setting, filling cystometry seems to show a slight increase in intravesical pressure, but Klevmark (1974, 1999) elegantly showed that this pressure increase is a function of the fact that cystometric filling is carried out at a greater-than-physiologic rate and that, at physiologic filling rates, there is essentially no increase in bladder pressure until bladder capacity is reached.

When the collagen component of the bladder wall increases, compliance decreases. This can occur with chronic inflammation, bladder outlet obstruction, neurologic decentralization, and various other types of injury. Bladder muscle hypertrophy, which can result from outlet obstruction, can also result in decreased compliance because hypertrophic muscle is said to be less elastic than normal detrusor; it also can synthesize increased amounts of collagen (Mostwin, 2006). **Once decreased compliance has occurred because of a replacement**

by collagen of other components of the stroma, it is generally unresponsive to pharmacologic manipulation.

Does the nervous system affect the normal bladder response to filling? At a certain level of bladder filling, **spinal sympathetic reflexes** facilitatory to bladder filling/storage are clearly evoked in animals, a concept developed over the years by de Groat and others (see Chapter 110) (de Groat et al., 1993; de Groat and Yoshimura, 2001; Chancellor and Yoshimura, 2002; Yoshimura and Chancellor, 2007; Zderic et al., 2002), who have also cited indirect evidence to support such a role in humans. **This inhibitory effect is thought to be mediated primarily by sympathetic modulation of cholinergic ganglionic transmission.** Through this reflex mechanism, **two other possibilities exist for promoting filling and storage.** One is neurally mediated stimulation of the predominantly α-adrenergic receptors (α_1) in the area of the smooth sphincter, the net result of which would be to cause an increase in resistance in that area. The second is neurally mediated stimulation of the predominantly β-adrenergic receptors (β_3 inhibitory) in the bladder body smooth musculature, which would cause a decrease in bladder wall tension, promoting bladder relaxation. McGuire et al. (1983) have also proposed a direct inhibition of detrusor motor neurons in the sacral spinal cord during bladder filling related to increased afferent pudendal nerve activity generated by receptors in the striated sphincter. **Good evidence also seems to support an inhibitory effect of other neurotransmitters (e.g., glycine, γ-aminobutyric acid, opioids, purines, the noradrenergic system) on the micturition reflex at various levels of the neural axis.** Bladder filling and consequent wall distention may also result in the release of factors from the urothelium that may influence contractility (e.g., acetylcholine, adenosine triphosphate, nitric oxide, prostaglandins, other peptides, as yet unidentified inhibitory factors). Despite these findings, current urodynamic technology does not accurately measure underlying detrusor wall tension (Habteyer et al., 2017).

Outlet Response During Filling

There is a gradual increase in proximal urethral pressure during bladder filling, contributed to at least by the striated sphincteric element and perhaps by the smooth sphincteric element as well. The increase in urethral pressure seen during the filling/storage phase of micturition can be correlated with an increase in efferent pudendal nerve impulse frequency and in electromyographic activity of the striated sphincter. This constitutes the efferent limb of a spinal somatic reflex, the so-called guarding reflex, which results in a gradual increase in striated sphincter activity during normal bladder filling and storage. Although it seems logical and compatible with neuropharmacologic, neurophysiologic, and neuromorphologic data to assume that the muscular component of the smooth sphincter also contributes to the change in urethral response during bladder filling, probably through sympathetically induced contraction, it is extremely difficult to prove this experimentally or clinically. The direct and circumstantial evidence in favor of such a hypothesis has been summarized by Andersson (2014), Andersson and Wein (2004), Birder et al. (2013), Brading (1999), and Wein and Barrett (1988).

The passive properties of the urethral wall warrant mention because these undoubtedly play a role in the maintenance of continence (Brading, 1999; Zinner et al., 1983). Urethral wall tension develops within the outer layers of the urethra; however, urethral pressure is a product not only of the active characteristics of smooth and striated muscle but also of the passive characteristics of the elastic, collagenous, and vascular components of the urethral wall because this tension must be exerted on a soft or plastic inner layer capable of being compressed to a closed configuration—the **“filler material”** representing the submucosal portion of the urethra. The softer and more pliable this area is, the less pressure is required by the tension-producing area to produce continence. Finally, whatever the compressive forces, the lumen of the urethra must be capable of being obliterated by a watertight seal. This **“mucosal seal mechanism”** explains why a thin-walled rubber tube requires less pressure to close an open end when the inner layer is coated with a fine layer of grease than when it is not; the latter case is akin to scarred or atrophic urethral mucosa.

Voiding With a Normal Bladder Contraction

Although many factors are involved in the initiation of micturition, in adults, **increased intravesical pressure producing the sensation of distention is primarily responsible for the initiation of normal voluntarily induced emptying of the LUT. Although the origin of the parasympathetic neural outflow to the bladder, the pelvic nerve, is in the sacral spinal cord, the actual coordinating center for the micturition reflex in an intact neural axis is in the rostral brainstem.** The complete neural circuit for normal micturition includes the ascending and descending spinal cord pathways to and from this area and the facilitatory and inhibitory influences from other parts of the brain, particularly the cerebral cortex. **The final step in voluntarily induced micturition involves inhibition of the somatic neural efferent activity to the striated sphincter and an inhibition of all aspects of any spinal sympathetic reflexes evoked during filling. Efferent parasympathetic pelvic nerve activity is ultimately what is responsible for a highly coordinated contraction of the bulk of the bladder smooth musculature.**

A decrease in outlet resistance occurs with adaptive shaping or funneling of the relaxed bladder outlet. Besides the inhibition of any continence-promoting reflexes that have occurred during bladder filling, the change in outlet resistance may also involve an active relaxation of the smooth sphincter area through a noradrenergic noncholinergic mechanism, proposed to be mediated by nitric oxide (Andersson, 2014; Andersson and Arner, 2004; Andersson and Wein, 2004; Birder et al., 2013). The adaptive changes that occur in the outlet are probably also due at least in part to the anatomic interrelationships of the smooth muscle of the bladder base and proximal urethra. Longitudinal smooth muscle continuity (see Chapter 110) (Mostwin, 2006) would promote shortening and widening of the proximal urethra during a coordinated emptying bladder contraction. Other reflexes elicited by bladder contraction and by the passage of urine through the urethra may reinforce and facilitate complete bladder emptying. Superimposed on these autonomic and somatic reflexes are complex, modifying supraspinal inputs from other central neuronal networks. These facilitatory and inhibitory impulses, which originate from several areas of the nervous system, allow the full conscious control of micturition in the adult.

Urinary Continence During Abdominal Pressure Increases

During voluntarily initiated micturition, the bladder pressure becomes higher than the outlet pressure, and certain adaptive changes occur in the shape of the bladder outlet with consequent passage of urine into and through the proximal urethra. One could reasonably ask: **Why do such changes not occur with increases in intravesical pressure that are similar in magnitude but that are produced only by changes in intra-abdominal pressure such as straining or coughing?** First, a coordinated bladder contraction does not occur in response to such stimuli, emphasizing the fact that increases in total intravesical pressure are by no means equivalent to emptying ability. Second, for urine to flow into and through the proximal urethra in an individual who does not have sphincteric incontinence, there must be (1) an increase in intravesical/detrusor pressure that is primarily a product of a coordinated, neurally mediated bladder contraction and that is (2) associated with characteristic tension and conformational changes in the bladder neck and proximal urethral areas.

Assuming that the bladder outlet is competent at rest, a major factor required for the prevention of urinary leakage during increases in intra-abdominal pressure is the presence of **at least equal pressure transmission to the proximal urethra (the mid-urethra as well in women) during such activity.** This phenomenon was first described by Enhorning (1961) and has been confirmed in virtually every urodynamic laboratory since that time. **Failure of this mechanism is an invariable correlate of effort-related urinary incontinence in women and men. The urethral closure pressure increases with increments in intra-abdominal pressure, indicating that active muscular function related to a reflex increase in striated sphincter activity or other factors that increase urethral resistance is also involved in preventing such leakage.** Tanagho (1978) was the first to provide direct evidence of this. A more complete description of the factors involved in sphincteric incontinence can be found later in this chapter, in Chapter 110, and in the work of Koelbl et al. (2013).

Sensory Aspects

Most of the afferent input from the bladder and urethra reaches the spinal cord through the pelvic nerve and dorsal root ganglia, and some reaches the spinal cord through the hypogastric nerve. Afferent input from the striated muscle of the sphincter and pelvic floor travels in the pudendal nerve. The most important afferents for initiating and maintaining normal micturition are those in the pelvic nerve, relaying to the sacral spinal cord. These convey impulses from tension, volume, and nociceptive receptors located in the serosal, muscle, and urothelial and suburothelial layers of the bladder and urethra. In a neurologically normal adult, the sensation of filling and distention, but not urgency or pain, develops during normal filling/storage and initiates the reflexes responsible for emptying/voiding (see Chapter 110) (Birder et al., 2013; Chancellor and Yoshimura, 2002; de Groat and Yoshimura, 2001; Morrison et al., 2005). Alterations in this finely tuned pathway can be responsible for significant alterations in LUT function.

Micturition Cycle: Simplification and Overview

Filling/Storage

Bladder accommodation during filling is a primarily passive phenomenon dependent on the elastic and viscoelastic properties of the bladder wall and the lack of parasympathetic excitatory input. An increase in outlet resistance occurs by means of the striated sphincter somatic guarding reflex. In some species, a sympathetic reflex also contributes to storage by (1) increasing outlet resistance through increased tension in the smooth sphincter, (2) inhibiting bladder contractility through an inhibitory effect on parasympathetic ganglia, and (3) causing a decrease in tension of bladder body smooth muscle. Continence is maintained during increases in intra-abdominal pressure by the intrinsic competence of the bladder outlet (bladder neck and proximal urethra/mid-urethra) and the pressure transmission ratio to this area with respect to the intravesical contents. A further increase in striated sphincter activity, on a reflex basis, is also contributory.

Emptying/Voiding

Emptying/voiding can be voluntary or involuntary and involves an inhibition of the spinal somatic and sympathetic reflexes and activation of the vesical parasympathetic pathways, the organizational center for which is in the rostral brainstem. Initially, there is a decrease in outlet resistance, mediated not only by the cessation of the somatic and sympathetic spinal reflexes but possibly also by a relaxing factor released by parasympathetic stimulation or by some effect of bladder smooth muscle contraction. A highly coordinated, parasympathetically induced contraction of the bulk of the bladder smooth musculature occurs, with shaping or funneling of the relaxed outlet, at least partially because of smooth muscle continuity between the bladder base and the proximal urethra. With amplification and facilitation of the bladder contraction from other peripheral reflexes and from spinal cord supraspinal sources, and in the absence of anatomic or functional obstruction between the bladder and urethral meatus, complete emptying occurs.

Abnormalities of Filling/Storage and Emptying/Voiding: Overview of Pathophysiology

Excluding psychological reasons, the pathophysiology of failure of the LUT in an adult to fill with or store urine adequately or to empty adequately must logically be secondary to reasons related to the bladder, the outlet, or a combination (Wein, 1981; Wein and Barrett, 1988). This division provides a logical rationale for discussion and classification of all types of LUT dysfunction (Box 111.1).

Box 111.1

Simple Functional Classification of Lower Urinary Tract Dysfunction

Failure to Store

Because of the bladder
Because of the outlet

Failure to Empty

Because of the bladder
Because of the outlet

There are some types of dysfunction that represent combinations of filling/storage and emptying/voiding abnormalities (e.g., detrusor overactivity and sphincter dyssynergia in a patient with a suprasacral spinal cord injury; DO during filling/storage, detrusor underactivity during emptying). However, within this scheme these have become readily understandable and detectable, and the treatment dilemmas have been logically described. Failure in either category is not absolute but more often is relative. The system can be easily expanded and made more detailed to include etiologic or specific urodynamic connotations

(Box 111.2). However, the simplified system is perfectly workable and avoids argument in complex situations in which the exact cause or mechanism for a dysfunction cannot be established.

Box 111.2

Expanded Functional Classification of Lower Urinary Tract Dysfunction

- I. Failure to store
  - A. Because of the bladder
    - 1. Overactivity
      - a. Involuntary contractions (detrusor overactivity)
        - (1) Neurologic disease, injury, or degeneration
        - (2) Bladder outlet obstruction
        - (3) Increased afferent input or sensitivity
        - (4) Inflammation
        - (5) Increased neurotransmitter release
        - (6) Increased sensitivity to transmitter
        - (7) Decreased inhibitory pelvic floor activity
        - (8) Idiopathic
      - b. Decreased compliance
        - (1) Neurologic disease or injury
        - (2) Fibrosis
        - (3) Bladder muscle hypertrophy
        - (4) Idiopathic
      - c. Combination
    - 2. Hypersensitivity
      - a. Inflammatory/infectious
      - b. Neurologic
      - c. Increased neurotransmitter release or sensitivity
      - d. Psychological
      - e. Idiopathic
    - 3. Underactivity (with retention and overflow incontinence)
    - 4. Combination
  - B. Because of the outlet

    1. Genuine stress urinary incontinence
        a. Lack of suburethral support
        b. Pelvic floor laxity, hypermobility
    2. Intrinsic sphincter deficiency
        a. Neurologic disease or injury
        b. Fibrosis
    3. Combination (genuine stress urinary incontinence and intrinsic sphincter deficiency)
  C. Combination (bladder and outlet factors)
  D. Fistula

II. Failure to empty
  A. Because of the bladder (underactivity)
    1. Neurogenic (includes iatrogenic causes)
    2. Myogenic
    3. Psychogenic
    4. Idiopathic
  B. Because of the outlet
    1. Anatomic
        a. Prostatic obstruction
        b. Bladder neck contracture
        c. Urethral stricture
        d. Urethral compression, fibrosis
    2. Functional
        a. Striated sphincter dyssynergia (neurogenic)
        b. Smooth sphincter dyssynergia or dysfunction (bladder neck dysfunction)
        c. Dysfunctional voiding (non-neurogenic)
  C. Combination

Using this concept, all aspects of urodynamic and video-urodynamic evaluation can be conceptualized regarding exactly what they evaluate in terms of either bladder or outlet activity during filling/storage or emptying/voiding (Table 111.1). Treatments can be classified under these broad categories as to whether they facilitate filling/storage or emptying/voiding and whether they do so by acting primarily on the bladder or on one or more components of the bladder outlet (Boxes 111.3 and 111.4).

TABLE 111.1

Urodynamics Simplified

	BLADDER	OUTLET
Filling/storage phase	Pves[a] Pdet[b] (FCMG[c])	UPP[d]
	DLPP[e]	VLPP[f]
Emptying phase	Pves[g] Pdet[h] (VCMG)[i]	FLUORO[j]
		MUPP[k]
		FLUORO[l]
		EMG[m]
	(_________________ _________________)	
	_____________ FLOW[n] _______________	
	_____________ RU[o] ____________________	

[a,b] Total bladder (Pves) and detrusor (Pdet) pressures during a filling cystometrogram (FCMG).

[c] Filling cystometrogram.

[d] Urethral pressure profilometry.

[e] Detrusor leak point pressure.

[f] Valsalva leak point pressure.

[g,h] Total bladder and detrusor pressures during a voiding cystometrogram (VCMG).

[i] Voiding cystometrogram.

[j] Fluoroscopy of outlet during filling/storage.

[k] Micturitional urethral pressure profilometry.

[l] Fluoroscopy of outlet during emptying.

[m] Electromyography of periurethral striated musculature.

[n] Flowmetry.

[o] Residual urine.

This functional conceptualization of urodynamics categorizes each study as to whether it examines bladder or outlet activity during the filling/storage or emptying phase of micturition. In this scheme, uroflow and residual urine integrate the activity of the bladder and the outlet during the emptying phase.

Box 111.3

Functional Categorization of Therapy to Facilitate Urine Storage/Bladder Filling

I. Bladder related (decreasing intravesical pressure, inhibitors, detrusor contractility, increasing bladder capacity)
  A. Behavioral therapy (including any or all of the following)
    1. Education
    2. Bladder training
    3. Timed bladder emptying or prompted voiding
    4. Fluid restriction
    5. Pelvic floor physiotherapy ± biofeedback
  B. Pharmacologic therapy (oral, intravesical, intradetrusor)
    1. Antimuscarinic agents
    2. Drugs with mixed actions
    3. β-Adrenergic agonists
    4. Botulinum toxin
    5. Calcium antagonists
    6. Potassium channel openers
    7. Prostaglandin inhibitors
    8. α-Adrenergic antagonists
    9. Tricyclic antidepressants; serotonin and norepinephrine reuptake inhibitors
    10. Dimethyl sulfoxide
    11. Polysynaptic inhibitors
    12. Capsaicin, resiniferatoxin, and similar agents
  C. Bladder overdistention
  D. Electrical stimulation (sacral neuromodulation, posterior tibial and other peripheral nerve stimulation)
  E. Acupuncture and electroacupuncture
  F. Interruption of innervation
    1. Very central (subarachnoid block)
    2. Less central (sacral rhizotomy, selective sacral rhizotomy)
    3. Peripheral motor and/or sensory
  G. Augmentation cystoplasty (autoaugmentation, bowel, tissue engineering)

II. Outlet related (increasing outlet resistance)
  A. Behavioral therapy (see I. A.)
  B. Electrical stimulation
  C. Pharmacologic therapy

        1. α-Adrenergic agonists
        2. Tricyclic antidepressants; serotonin and norepinephrine reuptake inhibitors
        3. β-Adrenergic antagonists, agonists
    D. Vaginal and perineal occlusive and/or supportive devices; urethral plugs
    E. Nonsurgical periurethral bulking
        1. Synthetics
        2. Tissue engineering
    F. Retropubic vesicourethral suspension ± prolapse repair (female)
    G. Sling procedures ± prolapse repair (female)
    H. Mid-urethral tapes ± prolapse repair (female)
    I. Perineal sling procedure (male)
    J. Artificial urinary sphincter
    K. Myoplasty (muscle transposition)
    L. Bladder outlet closure

III. Circumventing the problem
    A. Absorbent products
    B. External collecting devices
    C. Antidiuretic hormone–like agents
    D. Short-acting diuretics
    E. Intermittent catheterization
    F. Continuous catheterization
    G. Urinary diversion

Box 111.4

Functional Categorization of Therapy to Facilitate Bladder Emptying and Voiding

I. Bladder related (increasing intravesical pressure or facilitating/augmenting bladder contractility)
    A. External compression, Valsalva
    B. Promotion or initiating of reflex contraction
        1. Trigger zones or maneuvers
        2. Bladder "training"; tidal drainage

- C. Pharmacologic therapy (oral, intravesical)
  - 1. Parasympathomimetic agents
  - 2. Prostaglandins
  - 3. Blockers of inhibition
    - a. α-Adrenergic antagonists
    - b. Opioid antagonists
- D. Electrical stimulation
  - 1. Directly to the bladder or spinal cord
  - 2. Directly to the nerve roots
  - 3. Intravesical (transurethral)
  - 4. Neuromodulation
- E. Reduction cystoplasty
- F. Bladder myoplasty (muscle wrap)
- G. Tissue engineering

II. Outlet related (decreasing outlet resistance)

- A. At a site of anatomic obstruction
  - 1. Pharmacologic therapy—decrease prostate size or tone
    - a. α-Adrenergic antagonists
    - b. α-Reductase inhibitors
    - c. Luteinizing hormone–releasing hormone agonists/antagonists
    - d. Antiandrogens
  - 2. Prostatectomy, prostatotomy (diathermy, heat, laser, stapling)
  - 3. Bladder neck incision or resection
  - 4. Urethral stricture repair or dilation
  - 5. Intraurethral devices
  - 6. Balloon dilation of stricture/contracture
- B. At level of smooth sphincter
  - 1. Pharmacologic therapy
    - a. α-Adrenergic antagonists
    - b. β-Adrenergic agonists
    - c. Botulinum toxin (injection)
  - 2. Transurethral resection or incision
  - 3. Reconstruction
- C. At level of striated sphincter
  - 1. Behavioral therapy ± biofeedback
  - 2. Pharmacologic therapy
    - a. Benzodiazepines

        - b. Baclofen
        - c. Dantrolene
        - d. α-Adrenergic antagonists
        - e. Botulinum toxin (injection)
    - 3. Surgical sphincterotomy
    - 4. Pudendal nerve interruption
- D. Circumventing the underlying problem
    - 1. Intermittent catheterization
    - 2. Continuous catheterization
    - 3. Urinary diversion (conduit or reservoir)

Filling and Storage Failure

Absolute or relative failure of the bladder to fill with and store urine adequately results from bladder overactivity (involuntary contraction and/or decreased compliance), decreased outlet resistance, heightened or altered sensation, or a combination.

Bladder Overactivity

Overactivity of the bladder during filling/storage can be expressed as phasic involuntary contractions, as low compliance, or as a combination. Involuntary contractions are most commonly seen in association with neurologic disease or injury, bladder outlet obstruction, stress urinary incontinence (perhaps because of sudden entry of urine into the proximal urethra, eliciting a reflex contraction), or aging (probably related to neural degeneration), or they may be truly idiopathic. These bladder abnormalities may also lead to the development of micromotions, which may generate afferent activity leading to DO (Vahabi and Drake, 2015). However, they may also be associated with increased afferent input related to inflammation or irritation of the bladder or urethral wall or an increased sensitivity (decreased threshold of activation to a normal amount of transmitter). Excitatory neurotransmitters may be released from the urothelium during filling/storage and activate afferent receptors/nerves, ultimately resulting, in some individuals, in involuntary contractions or altered (heightened) sensation: a premature sensation of distention or fullness, true urgency (a sudden compelling desire to void, which is difficult to defer), or pain. If an individual has urgency urinary incontinence, it can be assumed that an involuntary contraction (DO) has occurred. The symptom of urgency without incontinence suggests DO, but this is often not demonstrable on urodynamic study. Conversely, urodynamically demonstrable DO may not be associated with clinically troublesome filling/storage symptoms.

The possible pathophysiologies of the symptom syndrome "overactive bladder" (defined by the International Continence Society [ICS] as urgency with or without urge incontinence, usually with frequency and nocturia) can be summarized as (1) reduced supraspontine inhibition, (2) damaged axonal paths in the spinal cord, (3) damaged axonal paths in the periphery, (4) loss of peripheral inhibition, (5) enhancement of excitatory neurotransmission in the micturition reflex pathway, (6) increased LUT afferent input, or (7) idiopathic. Staskin (2001) and Mostwin et al. (2005) also hypothesized that decreased stimulation from the pelvic floor can contribute to phasic bladder overactivity. **Decreased compliance** during filling/storage may be secondary to neurologic injury or disease, usually at a sacral or infrasacral level but may result from any process that impairs or destroys the viscoelastic or elastic properties of the bladder wall. As such, a compliance abnormality can be seen with increased collagen deposition resulting from longstanding bladder outflow obstruction.

Filling and Storage Failure Resulting From Altered Sensation

Bladder-related storage failure may also occur in the absence of overactivity because of increased afferent input from inflammation, irritation, other causes of hypersensitivity, and pain. The causes may be chemical, psychological, or idiopathic. One classic example is termed *bladder pain syndrome* (also known as *interstitial cystitis*; see Chapter 57). Increased afferent activity can be responsible for true DO (an involuntary contraction), true urgency without DO, a premature feeling of fullness or distention without urgency or DO, or the sensation of pain during filling.

Outlet Underactivity

Decreased outlet resistance may result from any process that damages the innervation of structural elements of the smooth or striated sphincter, or both, or damages or impairs the support of the bladder outlet in women. This process may occur with neurologic disease or injury, surgical or other mechanical trauma, or aging. Classically, sphincteric incontinence in a woman was categorized into relatively discrete entities: (1) so-called genuine stress incontinence and (2) intrinsic sphincter deficiency (ISD), originally described as “type III stress incontinence” (DeLancey, 1994; Koelbl et al., 2013; Mostwin et al., 2005) (see Chapters 110). Genuine stress incontinence in women was described as associated with hypermobility of the bladder outlet because of poor pelvic support and with an outlet that was competent at rest but lost its competence only during increases in intra-abdominal pressure. ISD described a nonfunctional or poorly functional bladder neck and proximal urethra at rest. The implication of classic ISD was that a surgical procedure designed to correct only urethral hypermobility would have a relatively high failure rate, as opposed to one designed to improve urethral coaptation and compression. The contemporary view is that most cases of effort-related incontinence in women involve varying proportions of support-related factors and ISD. It is possible to have outlet-related incontinence that is due only to ISD but not due solely to hypermobility or poor support—some ISD must exist.

Stress or effort-related urinary incontinence is a symptom that arises primarily from damage to muscles, nerves, or connective tissue, or a combination, within the pelvic floor (DeLancey et al., 2002; Koelbl et al., 2013; Mostwin et al., 2005; Welk et al., 2015). Urethral support is important in women, the urethra normally being supported by the action of the levator ani muscles through their connection to the endopelvic fascia of the anterior vaginal wall. Damage to the connection between this fascia and this muscle, damage to the relevant nerve supply, or direct muscle damage can influence continence. Bladder neck function is likewise important, and loss of normal bladder neck closure can result in incontinence despite normal urethral support. Previously, the urethra was sometimes ignored as a factor contributing to continence in women, and the site of continence was thought to be exclusively the bladder neck. However, in approximately 50% of continent women, urine enters the urethra during increases in abdominal pressure. The continence point in these women (highest point of pressure transmission) is at the mid-urethra.

Urethral hypermobility implies weakness of the pelvic floor support structures. During increases in intra-abdominal pressure, there is descent of the bladder neck and proximal urethra. If the outlet opens concomitantly, stress urinary incontinence ensues. In the classic form of urethral hypermobility, there is rotational descent of the bladder neck and urethra. The urethra may also descend without rotation (it shortens and widens), or the posterior wall of the urethra may be pulled (sheared) open while the anterior wall remains fixed. However, urethral hypermobility is often present in women who are not incontinent, and the mere presence of urethral hypermobility is insufficient to make a diagnosis of a sphincter abnormality unless urinary incontinence is also demonstrated. The **“hammock hypothesis”** of DeLancey (1994) proposes that for stress incontinence to occur with hypermobility, there must be a lack of stability of the suburethral supportive layer. This theory proposes that the effect of abdominal pressure increases on the normal bladder outlet, if the suburethral supportive layer is firm, is to compress the urethra rapidly and effectively. If the supportive suburethral layer is lax and/or movable, compression is not as effective. **Intrinsic sphincter dysfunction** denotes an intrinsic malfunction of the urethral sphincter mechanism. In its most overt form, it is characterized by a bladder neck that is open at rest and a low abdominal leak point pressure and urethral closure pressure (see Chapter 114) and is usually the result of prior surgery, trauma with scarring, or a neurologic lesion.

Urethral instability refers to the rare phenomenon of episodic decreases in outlet pressure unrelated to increases in bladder or abdominal pressure. Although rarely seemingly demonstrable, many authors believe that the decrease in urethral pressure usually represents simply the urethral component of what would otherwise be a bladder contraction/urethral relaxation in an individual whose bladder does not measurably contract, for either myogenic or neurogenic reasons. There has been a paucity of new data since the last edition of this text.

In theory at least, categories of outlet-related incontinence in men are similar to the categories in women. However, sphincteric incontinence in men is not associated with hypermobility of the bladder neck and proximal urethra but is similar to what is termed *intrinsic sphincter dysfunction* in women. There is almost no information on the topic of urethral instability in men.

The treatment of filling/storage abnormalities is directed toward inhibiting bladder contractility, decreasing sensory output, mechanically increasing bladder capacity, or increasing outlet resistance, the last either continuously or just during increases in intra-abdominal pressure.

Emptying and Voiding Failure

Absolute or relative failure to empty the bladder results from decreased bladder contractility (a decrease in magnitude, coordination, or duration), increased outlet resistance, or a combination.

Bladder Underactivity

Absolute or relative failure of bladder contractility may result from temporary or permanent failure or impairment in one of the neuromuscular mechanisms necessary for initiating and maintaining a normal detrusor contraction. Inhibition of the voiding reflex in a neurologically normal individual may also occur; it may be by a reflex mechanism secondary to increased afferent input, especially from the pelvic and perineal areas, or may be psychogenic. Iatrogenic causes such as surgery for colorectal, urologic, and gynecologic pathology may also lead to underactive bladder (Osman et al., 2014). Non-neurogenic causes also include impairment of bladder smooth muscle function, which may result from overdistention, various centrally or peripherally acting drugs, severe infection, or fibrosis. Diabetes mellitus may lead to bladder underactivity resulting from a combination of neuromuscular and vascular causes (Osman et al., 2014).

Outlet Overactivity or Obstruction

The ICS defines bladder outflow obstruction as a reduced urine flow rate and/or presence of a raised postvoid residual and an increased detrusor pressure. Pathologically increased outlet resistance is much more common in men than in women. Although it is most often secondary to anatomic obstruction, it may be secondary to a failure of relaxation or active contraction of the striated or smooth sphincter during bladder contraction (see Chapter 116). **Striated sphincter dyssynergia** is a common cause of functional (nonanatomic as opposed to fixed anatomic) obstruction in patients with neurologic disease or injury. Except for the true smooth sphincter contraction, which occurs in conjunction with autonomic dysreflexia, true dyssynergia at the level of the bladder neck–proximal urethra is unusual. Incomplete opening of an anatomically normal bladder neck during voluntary or involuntary voiding is termed *bladder neck dysfunction* and is an uncommon entity found almost exclusively in young and middle-aged men (also sometimes known as *primary bladder neck obstruction* or *dysfunctional bladder neck*) (see Chapter 116). Common causes of **anatomic outlet obstruction in men** include prostatic enlargement, bladder neck contracture, and urethral stricture. A common cause of bladder **outlet obstruction (BOO) in women** is compression or fibrosis after surgery for sphincteric incontinence. Regardless of cause, the typical hallmark of BOO is the urodynamic identification of an elevated detrusor pressure to produce a diminished flow across the outlet.

The treatment of emptying failure generally consists of maneuvers to increase intravesical/detrusor pressure, facilitate the micturition reflex, decrease outlet resistance, or a combination of these. Prompt intervention is recommended because long-term obstruction can lead to anatomic and functional changes in the detrusor (hypertrophy, collagen deposition, bladder diverticuli, detrusor overactivity) as well as alteration in neural networks (de Groat et al., 2015). If other means fail or are impractical, intermittent (or continuous) catheterization is an effective way to circumvent emptying failure.

Classification Systems

On the basis of the data obtained from the neurourologic evaluation, a given LUT dysfunction can be categorized in an ever-increasing number of descriptive systems. The **purpose of any classification system** should be to facilitate understanding and management and to avoid confusion among those who are concerned with the problem for which the system was designed. A good classification system should serve as **intellectual shorthand** and should convey, in a few key words or phrases, the essence of a clinical situation. An ideal system for all types of voiding dysfunction would include or imply several factors: (1) the conclusions reached from urodynamic testing, (2) expected clinical symptoms, and (3) approximate site and type of a neurologic lesion or lack of one. If the various categories accurately portray pathophysiology, treatment options should be obvious, and a treatment "menu" should be evident. **Most classification systems for voiding dysfunction were formulated primarily to describe dysfunction secondary to neurologic disease or injury. The ideal system should be applicable to all types of voiding dysfunction.** On the basis of the data obtained from the neurourologic evaluation, a given voiding dysfunction can be categorized in many descriptive systems. **No one system is perfect.** The major systems or types of systems in use are reviewed here with their advantages and applicability. Understanding the rationale and shortcomings of each system significantly improves knowledge of LUT function and dysfunction.

Functional System

Classification of voiding dysfunction can be formulated on a simple functional basis, describing the dysfunction in terms of whether the deficit produced is primarily one of the filling/storage or the emptying/voiding phase of micturition (see Box 111.1) (Wein, 1981; Wein and Barrett, 1988). The genesis of such a system was proposed initially by Scott's group (Quesada et al., 1968). This simple scheme assumes only that, whatever their differences, all "experts" would agree on the two-phase concept of micturition (filling/storage and emptying/voiding), on the simple overall mechanisms underlying the normality of each phase (see previous discussion), and on the possibilities for dysfunction.

The expansion of this concept to encompass all types of LUT dysfunction

(see Box 111.2) **and categorize urodynamic and video-urodynamic studies** (see Table 111.1) **has been previously discussed. In addition, all known treatments for voiding dysfunction may be classified easily under the broad categories of whether they facilitate filling/storage and emptying/voiding and whether they do so by an action primarily on the bladder or on one or more of the components of the bladder outlet** (see Boxes 111.3 and 111.4).

Failure in either category generally is not absolute but more often is relative. Such a functional system can easily be "expanded" and made more complicated to include etiologic or specific urodynamic connotations (see Box 111.4). However, the simplified system is workable and avoids argument in complex situations in which the exact cause or urodynamic mechanism for a voiding dysfunction cannot be definitively identified.

Proper use of the functional system for a given voiding dysfunction requires a reasonably accurate notion of what the urodynamic data show. However, **an exact diagnosis is not required for treatment. Some patients do not have only a discrete storage or emptying failure, and the existence of combination deficits must be recognized to use this system classification properly.** For example, the "classic" T10 paraplegic patient after spinal shock generally exhibits a relative failure of storage because of involuntary bladder contraction and a relative failure to empty the bladder because of striated sphincter dyssynergia. With such a combination deficit, to use this classification system as a guide to treatment relies on the assumption that one of the deficits is primary and that significant improvement will result from its treatment alone or that the voiding dysfunction can be converted primarily to a disorder of either storage or emptying by means of nonsurgical or surgical therapy. The resultant deficit can then be treated or circumvented. Using this example, the combined deficit in a patient with T10 paraplegia can be converted primarily to a storage failure by procedures directed at the dyssynergic striated sphincter; the resultant storage failure (secondary to involuntary contraction) can be circumvented (in a man) with an external collecting device. Alternatively, the deficit can be converted primarily to an emptying failure by pharmacologic or surgical measures designed to abolish or reduce the involuntary contraction, and the resultant emptying failure can be circumvented with clean intermittent catheterization. Other examples of combination deficits include impaired bladder contractility or overactivity with sphincter dysfunction, BOO with DO, BOO with sphincter malfunction, and detrusor filling/storage overactivity with impaired emptying contractility.

One advantage of this functional classification is that it allows the clinician the liberty of "playing" with the system to suit his or her own preferences without an alteration in the basic concept of "keep it simple but accurate and informative." For instance, one could easily substitute the terms *overactive* or *oversensitive bladder* and *underactive outlet* for *because of the bladder* and *because of the outlet* under "Failure to Store" in Box 111.1. One could choose to categorize the bladder reasons for overactivity (see Box 111.2) further in terms of neurogenic, myogenic, or anatomic causes and subcategorize neurogenic further in terms of decreased inhibitory control, increased afferent activity, and increased sensitivity to efferent activity. The system is flexible.

The classification system proposed by the ICS (Box 111.5) is **an extension of a urodynamic classification system.** The storage and voiding phases of micturition are described separately, and, within each phase, various designations are applied to describe bladder and urethral function (Abrams et al., 1988, 1992). Some of the definitions were changed by the standardization subcommittee of the ICS in 2002, and the relevant changes are indicated here (Abrams et al., 2002, 2003). **Normal bladder function during filling/storage implies no significant increases in detrusor pressure (stability). Overactive detrusor function indicates the presence of "involuntary detrusor contractions during the filling phase, which may be spontaneous or provoked."** If the condition is caused by neurologic disease, the term ***neurogenic detrusor overactivity*** is applied. If not, the term ***idiopathic detrusor overactivity*** is applied. **Bladder sensation** can be categorized only in qualitative terms as indicated. **Bladder capacity and compliance** (Δ volume/Δ pressure) are cystometric measurements. Bladder capacity can refer to cystometric capacity, maximum cystometric capacity, or maximum anesthetic cystometric capacity (Abrams et al., 2002). **Normal urethral function during filling/storage indicates a positive urethral closure pressure (urethral pressure minus bladder pressure) even with increases in intra-abdominal pressure, although it may be overcome by DO. Incompetent urethral function during filling/storage** implies urine leakage in the absence of a detrusor contraction. This leakage may be due to genuine stress incontinence, intrinsic sphincter dysfunction, a combination, or an involuntary decrease in urethral pressure in the absence of detrusor contraction.

Box 111.5

International Continence Society Classification

STORAGE PHASE	VOIDING PHASE
BLADDER FUNCTION	**BLADDER FUNCTION**
Detrusor activity	Detrusor activity
Normal or stable	Normal
Overactive	Underactive
Neurogenic	Acontractile
Idiopathic	Areflexic
Bladder sensation	**URETHRAL FUNCTION**
Normal	Normal
Increased or hypersensitive	Abnormal
Reduced or hyposensitive	Mechanical obstruction
Absent	Overactivity
Bladder capacity	Dysfunctional voiding
Normal	Detrusor sphincter dyssynergia
High	Nonrelaxing urethral sphincter dysfunction
Low	
BLADDER COMPLIANCE	
Normal	
High	
Low	
URETHRAL FUNCTION	
Normal closure mechanism	
Incompetent closure mechanism	

Modified from Abrams P, Blaivas J, Stanton S, et al.: ICS standardization of terminology of LUT function. *Scand J Urol Nephrol* 114:5–19, 1988; Abrams P, Blaivas J, Stanton S, et al.: ICS 6th report on the standardization of terminology of LUT function. *Neurol Urodyn* 11:593–603, 1992; and Abrams P, Cardozo L, Fall M, et al.: The standardization of terminology in LUT function: report from the standardization subcommittee of the International Continence Society. *Neurol Urodyn* 21:167–178, 2002.

During the voiding/emptying phase of micturition, normal detrusor activity implies voiding by a voluntarily initiated sustained contraction that leads to complete bladder emptying within a normal time span. An **underactive detrusor** defines a contraction of inadequate magnitude or duration, or both, to empty the bladder within a normal time span. An **acontractile detrusor** is one that cannot be demonstrated to contract during urodynamic testing. **Areflexia** is defined as acontractility secondary to an abnormality of neural control, implying the complete absence of centrally coordinated contraction. **Normal urethral function** during voiding indicates a urethra that opens and is continuously relaxed to allow bladder emptying at a normal pressure. **Abnormal urethral function during voiding** may be due to either mechanical obstruction or urethral overactivity. **Dysfunctional voiding** describes an intermittent or fluctuating flow rate secondary to involuntary intermittent contractions of the periurethral striated muscle in neurologically normal individuals. **Detrusor sphincter dyssynergia** defines a detrusor contraction concurrent with an involuntary contraction of the urethral or periurethral striated muscle, or both. **Nonrelaxing urethral sphincter obstruction** usually occurs in individuals with a neurologic lesion and is characterized by a nonrelaxing obstructing urethra resulting in reduced urine flow.

LUT dysfunction in a patient with classic T10-level paraplegia after spinal shock has passed would be classified in the ICS system as follows:

- Storage phase: overactive neurogenic detrusor function, absent sensation, low capacity, normal compliance, normal urethral closure function
- Voiding phase: overactive obstructive urethral function, overactive detrusor function

The micturition dysfunction of a patient with stroke and urgency incontinence would most likely be classified during storage as overactive neurogenic detrusor function, normal sensation, low capacity, normal compliance, and normal urethral closure function. During voiding, the dysfunction would be classified as normal detrusor activity and normal urethral function, assuming that no anatomic obstruction existed.

Urodynamic Classification

As urodynamic techniques have become more accepted and sophisticated, systems of classification have evolved solely on the basis of objective urodynamic data (Box 111.6). Among the first to popularize this concept were Krane and Siroky (1984). When exact urodynamic classification is possible, such a system can provide an exact description of the voiding dysfunction that occurs. If a normal or overactive detrusor exists with coordinated smooth and striated sphincter function and without anatomic obstruction, normal bladder emptying should occur. Neurogenic **detrusor overactivity** is most commonly associated with neurologic lesions above the sacral spinal cord. **Striated sphincter dyssynergia** is most commonly seen after complete suprasacral spinal cord injury, following the period of spinal shock. **Smooth sphincter dyssynergia** is seen most classically in autonomic hyperreflexia (see Chapter 116) when it is characteristically associated with DO and striated sphincter dyssynergia. **Detrusor areflexia** (this category includes acontractile and areflexic bladder) may be secondary to bladder muscle decompensation or to various other conditions that produce inhibition at the level of the brainstem micturition center, the sacral spinal cord, bladder ganglia, or bladder smooth muscle. Patients with a voiding dysfunction secondary to detrusor areflexia generally attempt bladder emptying by abdominal straining, and their continence status and the efficiency of their emptying efforts are determined by the status of their smooth and striated sphincter mechanisms.

Box 111.6

Urodynamic Classification

Detrusor Hyperreflexia (or Normoreflexia)

Coordinated sphincters
Striated sphincter dyssynergia
Smooth sphincter dyssynergia
Nonrelaxing smooth sphincter

Detrusor Areflexia

Coordinated sphincters
Nonrelaxing striated sphincter
Denervated striated sphincter
Nonrelaxing smooth sphincter

Modified from Krane RJ, Siroky MB: Classification of voiding dysfunction: value of classification systems. In Barrett DM, Wein AJ, editors: *Controversies* *in neuro-urology,* New York, 1984, Churchill Livingstone, pp 223–238.

This classification system is easiest to use when detrusor overactivity or normoreflexia exists. A patient with typical T10-level paraplegia after spinal shock exhibits detrusor overactivity, smooth sphincter synergia, and striated sphincter dyssynergia. When a voluntary or a DO contraction cannot be elicited, the system is more difficult to use because it is not appropriate to speak of true sphincter dyssynergia in the absence of an opposing bladder contraction. There are many variations and extensions of such a system. **Such systems can work well only when total urodynamic agreement exists among classifiers. There are many dysfunctions that do not fit neatly into a urodynamic classification system that is agreed on by all experts. Compliance is not mentioned in this particular version, nor is sensation or the concept of deficient, but not absent, detrusor contractile function.** As sophisticated urodynamic technology and understanding improve, this type of classification system may be more commonly used. The ICS system (see previous discussion) is a logical and more complete extension of such a system.

Lapides Classification

Lapides (1970) contributed significantly to the classification and care of patients with neuropathic voiding dysfunction by slightly modifying and popularizing a system originally proposed by McLellan (1939) (Box 111.7). Lapides' classification differs from that of McLellan in only one respect, and that is the division of the group of "atonic neurogenic bladder" into sensory neurogenic and motor neurogenic bladder. This is a familiar system to urologists and nonurologists because it describes in recognizable shorthand the clinical and cystometric conditions of many types of neurogenic voiding dysfunction.

Box 111.7

Lapides Classification

Sensory neurogenic bladder
Motor paralytic bladder (motor neurogenic bladder)
Uninhibited neurogenic bladder
Reflex neurogenic bladder

Autonomous neurogenic bladder

A sensory neurogenic bladder results from disease that selectively interrupts the sensory fibers between the bladder and the spinal cord or the afferent tracts to the brain. **Diabetes mellitus, tabes dorsalis, and pernicious anemia** are the diseases most responsible. The first clinical changes are described as impaired sensation of bladder distention. Unless voiding is initiated on a timed basis, varying degrees of bladder overdistention can result with hypotonicity. If bladder decompensation occurs, significant amounts of residual urine result, and at that time the cystometric curve generally demonstrates a large-capacity bladder with a flat, high-compliance, low-pressure filling curve.

A **motor paralytic bladder** results from disease processes that destroy the parasympathetic motor innervation of the bladder. **Extensive pelvic surgery or trauma** may produce this. **Herpes zoster** has been listed as a cause as well, but more recent evidence suggests that the voiding dysfunction seen with herpes may be related more to a problem with afferent input (see Chapter 116). The early symptoms of a motor paralytic bladder may vary from painful urinary retention to only a relative inability to initiate and maintain normal micturition. Early cystometric filling is normal but without a voluntary bladder contraction at capacity. Chronic overdistention and decompensation may occur, resulting in a large-capacity bladder with a flat, low-pressure filling curve; a large amount of residual urine may result.

An **uninhibited neurogenic bladder** was described originally as resulting from injury or disease to the “corticoregulatory tract.” The sacral spinal cord was presumed to be the micturition reflex center, and this corticoregulatory tract was believed normally to exert an inhibitory influence on the sacral micturition reflex center. A destructive lesion in this tract would then result in overfacilitation of the micturition reflex. **Cerebrovascular accident, brain or spinal cord tumor, Parkinson disease, and demyelinating disease** were listed as the most common causes in this category. The voiding dysfunction is most often characterized symptomatically by frequency, urgency, and urge incontinence and urodynamically by normal sensation with involuntary contraction at low filling volumes. Residual urine is characteristically low unless anatomic outlet obstruction or true smooth or striated sphincter dyssynergia occurs. The patient generally can initiate a bladder contraction voluntarily but is often unable to do so during cystometry because sufficient urine storage cannot occur before involuntary contraction is stimulated.

Reflex neurogenic bladder refers to the post–spinal shock condition that exists after complete interruption of the sensory and motor pathways between the sacral spinal cord and the brainstem. Most commonly, this condition occurs in **traumatic spinal cord injury and transverse myelitis,** but it may occur with **extensive demyelinating disease or any process that produces significant suprasacral (cord) spinal cord destruction.** Typically, there is no bladder sensation, and there is inability to initiate voluntary micturition. Incontinence without sensation generally results from low-volume involuntary contraction. Striated sphincter dyssynergia is the rule. This type of lesion is essentially equivalent to a complete upper motor neuron (UMN) lesion in the Bors-Comarr system (see later in this chapter).

An autonomous neurogenic bladder results from complete motor and sensory separation of the bladder from the sacral spinal cord. This condition may be caused by **any disease that destroys the sacral cord or causes extensive damage to the sacral roots or pelvic nerves.** There is inability to initiate micturition voluntarily, no bladder reflex activity, and no specific bladder sensation. This type of bladder is equivalent to a complete lower motor neuron (LMN) lesion in the Bors-Comarr system and is the type of dysfunction seen in patients with spinal shock. The characteristic cystometric pattern is initially similar to the late stages of the motor or sensory paralytic bladder, with a marked shift to the right of the cystometric filling curve and a large bladder capacity at low intravesical pressure. However, decreased compliance may develop, secondary either to chronic inflammatory change or to the effects of denervation/decentralization with secondary neuromorphologic and neuropharmacologic reorganizational changes. Emptying capacity may vary widely, depending on the ability of the patient to increase intravesical pressure and on the resistance offered during this increase by the smooth and striated sphincters.

These classic categories in their usual settings are generally understood and remembered, and this is why this system provides an excellent framework for teaching some fundamentals of neurogenic voiding dysfunction to students and nonurologists. However, **many patients do not fit exactly into one or another category.** Gradations of sensory, motor, and mixed lesions occur, and the patterns produced after different types of peripheral denervation/defunctionalization may vary widely from the patterns that are classically described. **The system is applicable only to neuropathic dysfunction.**

Bors and Comarr (1971) made a remarkable contribution by logically deducing a classification system from clinical observation of their patients with traumatic spinal cord injury (Box 111.8). **This system, primarily of historical interest at present, applies only to patients with neurologic dysfunction and considers three factors: (1) the anatomic localization of the lesion, (2) the neurologic completeness or incompleteness of the lesion, and (3) whether LUT function is *balanced* or *unbalanced*.** The last terms are based solely on the percentage of residual urine relative to bladder capacity. **Unbalanced** signifies the presence of greater than 20% residual urine in a patient with a UMN lesion or 10% in a patient with an LMN lesion. This relative residual urine volume was ideally meant to imply coordination (synergy) or dyssynergia between the smooth and the striated sphincters of the outlet and the bladder during bladder contraction or during attempted micturition by abdominal straining or the Credé maneuver. The determination of the completeness of the lesion is made on the basis of a thorough neurologic examination.

Box 111.8

Bors-Comarr Classification

- Sensory neuron lesion
  - Incomplete, balanced
  - Complete, balanced
- Motor neuron lesion
  - Balanced
  - Imbalanced
- Sensorimotor neuron lesion
  - Upper motor neuron lesion
    - Complete, balanced
    - Complete, imbalanced
    - Incomplete, balanced
    - Incomplete, imbalanced
  - Lower motor neuron lesion
    - Complete, balanced
    - Complete, imbalanced
    - Incomplete, balanced

        Incomplete, imbalanced
    Mixed lesion
        Upper somatomotor neuron, lower visceromotor neuron
        Lower somatomotor neuron, upper visceromotor neuron
        Normal somatomotor neuron, lower visceromotor neuron

The system erroneously assumes that the sacral spinal cord is the primary reflex center for micturition. **LMN** implies collectively the preganglionic and postganglionic parasympathetic autonomic fibers that innervate the bladder and outlet and originate as preganglionic fibers in the sacral spinal cord. The term is used in an analogy to efferent somatic nerve fibers such as those of the pudendal nerve, which originate in the same sacral cord segment but terminate directly on pelvic floor striated musculature without the interposition of ganglia. **UMN** is used in a similar analogy to the somatic nervous system to describe the descending autonomic pathways above the sacral spinal cord (the origin of the motor efferent supply to the bladder).

In this system, **UMN bladder** refers to the pattern of micturition that results from an injury to the suprasacral spinal cord after the period of spinal shock has passed, assuming that the sacral spinal cord and the sacral nerve roots are intact and that the pelvic and pudendal nerve reflexes are intact. **LMN bladder** refers to the pattern resulting if the sacral spinal cord or sacral roots are damaged and the reflex pattern through the autonomic and somatic nerves that emanate from these segments is absent. This system implies that if skeletal muscle spasticity exists below the level of the lesion, the lesion is above the sacral spinal cord and is by definition a UMN lesion. This type of lesion is characterized by involuntary bladder contraction during filling. If flaccidity of the skeletal musculature below the level of a lesion exists, an LMN lesion is assumed to be present, implying that detrusor areflexia is present. Exceptions occur and are classified in a **“mixed lesion group”** characterized either by involuntary bladder contraction with a flaccid paralysis below the level of the lesion or by detrusor areflexia with spasticity or normal skeletal muscle tone neurologically below the lesion level.

The use of this system is illustrated as follows. A **“UMN lesion, complete, imbalanced”** implies a neurologically complete lesion above the level of the sacral spinal cord that results in skeletal muscle spasticity below the level of the injury. Involuntary bladder contraction occurs during filling, but a residual urine volume of greater than 20% of the bladder capacity is left after bladder contraction, implying obstruction in the area of the bladder outlet during the involuntary detrusor contraction. This obstruction is generally due to striated sphincter dyssynergia, typically occurring in patients who are paraplegic or quadriplegic with lesions between the cervical and the sacral spinal cord. Smooth sphincter dyssynergia may be seen as well in patients with lesions above the level of T6, usually associated with autonomic dysreflexia (see Chapter 116). An **“LMN lesion, complete, imbalanced”** implies a neurologically complete lesion at the level of the sacral spinal cord or of the sacral roots, resulting in skeletal muscle flaccidity below that level. Detrusor areflexia results, and whatever measures the patient may use to increase intravesical pressure during attempted voiding are insufficient to decrease residual urine to less than 10% of bladder capacity.

This classification system applies best to spinal cord injury patients with complete neurologic lesions after spinal shock has passed. It is difficult to apply to patients with multicentric neurologic disease and cannot be used at all for patients with non-neurologic disease. The system fails to reconcile the clinical and urodynamic variability exhibited by patients who, by neurologic examination alone, seem to have similar lesions. The period of spinal shock that immediately follows severe cord injury is generally associated with bladder areflexia, whatever the status of the sacral somatic reflexes. Temporary or permanent changes in bladder or outlet activity during filling/storage and emptying/voiding may occur as a result of numerous factors, such as chronic overdistention, infection, and reinnervation or reorganization of neural pathways after injury or disease; such changes make it **impossible to predict LUT activity accurately solely on the basis of the level of the neurologic lesion.** Finally, although the terms *balanced* and *imbalanced* are helpful in that they describe the presence or absence of a certain relative percentage of residual urine, they do not imply the true functional significance of a lesion, which depends on the potential for damage to the lower or upper urinary tracts and on the social and vocational disability that results.

Hald-Bradley Classification

Hald and Bradley (1982) described what they termed a simple *neurotopographic classification* (Box 111.9). The system is of historical interest only. A **supraspinal lesion** is characterized by synergy between detrusor contraction and the smooth and striated sphincters, but defective inhibition of the voiding reflex exists. Involuntary bladder contraction generally occurs, and sensation is usually preserved. However, depending on the site of the lesion, detrusor areflexia and defective sensation may be seen. A **suprasacral spinal lesion** is roughly equivalent to what is described as a UMN lesion in the Bors-Comarr classification. An **infrasacral lesion** is roughly equivalent to an LMN lesion. **Peripheral autonomic neuropathy** is most frequently encountered in patients with diabetes and is characterized by deficient bladder sensation, gradually increasing residual urine, and ultimate decompensation with loss of detrusor contractility. A **muscular lesion** can involve the detrusor, the smooth sphincter, or any portion, or all, of the striated sphincter. The resultant dysfunction depends on which structure is affected. Detrusor dysfunction is the most common and generally results from decompensation after long-standing bladder outlet obstruction. In my opinion, this system is as confusing as the word *neurotopographic* and adds little to the understanding of LUT dysfunction.

Muscular lesion

Bradley Classification

Bradley's “loop system” of classification is a primarily neurologic system based on his conceptualization of central nervous system control of the LUT that identifies four neurologic “loops” (Hald and Bradley, 1982). Dysfunctions are classified according to the loop affected. Occasional reference is made to this system, primarily by nonurologists.

Loop 1 consists of neuronal connections between the cerebral cortex and the pontine mesencephalic micturition center; this coordinates voluntary control of the detrusor reflex. **Loop 1 lesions** are seen in conditions such as **brain tumor, cerebrovascular accident or disease, and cerebral atrophy with dementia.** The final result is characteristically **involuntary bladder contractions.**

Loop 2 includes the intraspinal pathway of detrusor muscle afferents to the brainstem micturition center and the motor impulses from this center to the sacral spinal cord. Loop 2 is thought to coordinate and provide for a detrusor reflex of adequate temporal duration to allow complete voiding. Partial interruption by spinal cord injury results in a detrusor reflex of low threshold and in poor emptying with residual urine. **Spinal cord transection of loop 2 acutely produces detrusor areflexia and urinary retention—spinal shock. After this has passed, involuntary bladder contractions result.**

Loop 3 consists of the peripheral detrusor afferent axons and their pathways in the spinal cord; these terminate by synapsing on pudendal motor neurons that ultimately innervate periurethral striated muscle. Loop 3 was thought to provide a neurologic substrate for coordinated reciprocal action of the bladder and striated sphincter. **Loop 3 dysfunction could be responsible for detrusor striated dyssynergia or involuntary sphincter relaxation.**

Loop 4 consists of two components. Loop 4A is the suprasacral afferent and efferent innervation of the pudendal motor neurons to the periurethral striated musculature. Loop 4B consists of afferent fibers from the periurethral striated musculature that synapse on pudendal motor neurons in Onuf nucleus—the segmental innervation of the periurethral striated muscle. Bradley conceptualized that, in contrast to the stimulation of detrusor afferent fibers, which produced inhibitory postsynaptic potentials in pudendal motor neurons through loop 3, pudendal nerve afferents produced excitatory postsynaptic potentials in those motor neurons through loop 4B. These provided for contraction of the periurethral striated muscle during bladder filling and urine storage. The related sensory impulses arise from muscle spindles and tendon organs in the pelvic floor musculature. **Loop 4 provides for volitional control of the striated sphincter.** Abnormalities of the suprasacral portion result in abnormal responses of the pudendal motor neurons to bladder filling and emptying, manifested as detrusor striated sphincter dyssynergia and/or loss of the ability to contract the striated sphincter voluntarily.

The Bradley system is sophisticated and reflects the ingenuity and neurophysiologic expertise of its originator, a neurologist. For neurologists, this method may be an excellent way to conceptualize the neurophysiology involved, assuming that there is agreement on the existence and significance of all four loops—a big assumption. Most urologists find this system difficult to use for many types of neurogenic LUT dysfunction and not applicable to non-neurogenic LUT dysfunction. Urodynamically, it may be extremely difficult to test the intactness of each loop system, and multicentric and partial lesions are difficult to describe.

Evaluation and Management of Women With Urinary Incontinence and Pelvic Prolapse

---

Alvaro Lucioni MD, Kathleen C. Kobashi MD

Definition and Impact of Pelvic Floor Disorders

Introduction

Pelvic floor disorders (PFDs) include urinary incontinence (UI), fecal incontinence, and pelvic organ prolapse (POP). With the increasing prevalence and health care costs related to evaluation and treatment of PFDs, understanding these disorders is of utmost importance.

The International Urogynecological Association (IUGA) and the International Continence Society (ICS) define urinary incontinence (UI) as the complaint of the involuntary loss of urine (Abrams et al., 2002; Haylen et al., 2010). There are a variety of different types of UI that include stress urinary incontinence (SUI), urgency urinary incontinence (UUI), mixed urinary incontinence (MUI), nocturnal enuresis, and postural, continuous, insensible, and coital incontinence. Table 112.1 lists the current IUGA/ICS nomenclature regarding urinary incontinence symptoms (Abrams et al., 2002; Abrams et al., 2009b; Haylen et al., 2010). The terminology continues to adjust to reflect the evolving understanding of the condition. The importance of this flexibility has been realized and acknowledged by leaders in the subspecialty of pelvic floor medicine (Chapple, 2009). Accordingly, the IUGA/ICS terminology has been updated since its inception and most recently has been expanded to include not only terminology for lower urinary tract (LUT) function and urodynamics (UDS), but also pelvic organ prolapse, lower urinary tract pain, sexual dysfunction, anorectal dysfunction, and pelvic imaging (Haylen et al., 2010).

TABLE 112.1

Standard International Urogynecological Association/International Continence Society Terminology of Urinary Incontinence Symptoms

TERMINOLOGY	DESCRIPTION
Urinary incontinence	Complaint of any involuntary leakage of urine
Stress urinary incontinence	Complaint of involuntary leakage on effort or exertion, or on sneezing or coughing
Urgency	Complaint of a sudden compelling desire to pass urine, which is

	difficult to defer
Urgency urinary incontinence	Complaint of involuntary leakage accompanied by or immediately preceded by urgency
Postural incontinence	Complaint of voluntary loss of urine associated with change of body position, for example, rising from a seated or lying position
Nocturnal enuresis	Complaint of involuntary loss of urine that occurs during sleep
Mixed incontinence	Complaint of involuntary leakage associated with urgency and also with exertion, effort, sneezing, or coughing
Continuous urinary incontinence	Complaint of continuous leakage
Insensible incontinence	Complaint of urinary incontinence when the woman has been unaware of how it occurred
Coital incontinence	Complaint of involuntary loss of urine with coitus

From Abrams P, Cardozo L, Fall M, et al. The standardisation of terminology of lower urinary tract function: Report from the Standardisation Sub-Committee of the International Continence Society. *Neurourol Urodyn* 21:167–178, 2002. (reprinted in *Urology* 61:37-49, 2003); Haylen BT, de Ridder D, Freeman RM, et al. An International Urogynecological Association (IUGA)/International Continence Society (ICS) joint report on the terminology for female pelvic floor dysfunction. *Neurourol Urodyn* 29:4–20, 2010.

UI is a common condition that affects all sectors of the population. The National Health and Nutrition Examination Survey of 2001 estimated the prevalence of SUI, UUI, MUI, and any type of incontinence to be 23.7%, 9.9%, 14.5%, and 49.2%, respectively (Minassian et al., 2008). The risk of UI increases with age, and with the aging population in the United States and worldwide, the impact of UI on society is expected to increase. UI is also prevalent in young women, with approximately 50% of adolescent and pregnant women younger than 25 years of age reporting some degree of UI (Jean-Michel et al., 2018). Women who participate in elite high-level sports have been noted to have three times the prevalence of urinary incontinence compared with controls (Carvalhais et al., 2018). Several studies have also implicated race as a potential risk factor for UI, with the odds of pure SUI being at least 2.5-fold higher in white and Mexican-American women than in black women (Dooley et al., 2008). Brazilian women have been reported to have an incidence of SUI of 39.3 × 1000 person-years (Tamanini et al., 2018). In Taiwan, 18.7% of women 29 to 59 years of age and 29.8% of women older than 60 years of age reported having SUI (Chang et al., 2017).

Pelvic organ prolapse (POP) refers to a falling, slipping, or downward displacement of a compartment or organ. Though the IUGA/ICS joint report on terminology establishes POP primarily as a definition of anatomic change, the diagnosis of POP requires clear clinical evidence that a woman is having symptoms related to the downward displacement of a pelvic organ (Haylen et al., 2016). Potential symptoms may include vaginal bulging, pelvic pressure, bleeding and/or discharge, need to splint or perform digitation for comfort or evacuation, and low backache. POP may have an effect on bladder, bowel, and sexual function. Lower urinary tract symptoms (LUTS) related to POP may vary from obstructive symptoms such as hesitancy, slow stream, intermittency, straining to void, feeling of incomplete bladder emptying, urgency, and position-dependent micturition to UI of a variety of types, such as SUI, UUI, and MUI. Anorectal dysfunction symptoms related to POP may include constipation, a sensation of incomplete bowel emptying, a need to splint or strain to evacuate, and fecal urgency with or without incontinence. Like incontinence, multiple risks factors for POP have been identified, including age, parity, genetics, estrogen deficiency, decreased pelvic floor muscle strength, smoking, cancer, and diabetes (Tamanini et al., 2018).

The impact of PFDs is far-reaching, carrying the potential to significantly affect a patient's quality of life (QoL), notwithstanding the psychological burden that can result from having any PFD. Additionally, PFDs can result in a tremendous cost to the individual and to society. Hu et al. estimated that the evaluation and management of UI and productivity lost as a result of the condition led to a $19.5 billion (year 2000 dollars) cost to society, although sensitivity analysis suggested a potential cost range of $9.32 to $28 billion (Hu et al., 2004). Reports have demonstrated that medical expenditures related to UI in the female Medicare population nearly doubled between 1992 and 1998, primarily as a result of increased outpatient expenditure from 9.1% to 27.3% of total Medicare costs in approximately the same timeframe (Anger et al., 2006a,b; Thom et al., 2005). The impact of PFDs on society goes further than evaluation and treatment costs. In a 2005 multinational study, the annual cost-of-illness estimate for UUI in the United States was $66 billion in 2007 US dollars (Milsom et al., 2014). In a retrospective study utilizing a 2001 to 2011 database, employees with UUI had 30% higher sick leave and 74% higher short-term disability costs (Kleinman et al., 2014). Work to mitigate this increase in cost is under way. Vermeulen et al. showed that a model in which primary care providers had an increased active role in the care of women 55 years of age or older demonstrated a significant improvement in the women's quality adjusted life-years (Vermeulen et al., 2016). Conversely, a mobile application that allowed for self-management of SUI with pelvic floor muscle training demonstrated a significant reduction in costs and improvement in quality adjusted life-years (Nyström et al., 2018).

The advent of social media and newer electronic tools has and will continue to dramatically increase the awareness of PFDs among affected populations and their health care providers. Additionally, a growing realization regarding the importance of QoL optimization has driven a new focus in the field of pelvic floor medicine. Tremendous research endeavors are under way to improve our understanding of the pathophysiology of PFDs in an effort to improve both diagnostic and therapeutic techniques. The importance of evidence-based medicine and meticulous follow-up of patients is driving improvement in the science on which advancements in this subspecialty of urology are being made.

Diagnostic Evaluation

General Considerations

A recent upsurge in research efforts has resulted in the emergence of new diagnostic and therapeutic techniques to address PFDs. As QoL impact has become a focus, much of current research efforts include detailed QoL assessment and attempts to quantify and assess the relationship between PFDs and their effects on QoL. Correlating the bother caused by a given PFD with the risks associated with available therapies is an important consideration. The purpose of evaluation of patients with UI includes documentation and characterization of the UI; consideration of the differential diagnosis; prognostication; and facilitation of treatment selection (Dmochowski et al., 2010). Additionally, proper evaluation helps assess symptom bother and establish a patient's expectations of potential outcomes so as to balance the degree of bother with the risks associated with available therapies for the individual patient (Kobashi et al., 2017).

The type of UI affecting an individual must be defined and quantified to guide proper treatment planning. Transient or unrelated conditions that can cause leakage should be identified before proceeding with definitive therapy. Table 112.2 contains a mnemonic of transient causes of UI (Resnick, 1984).

The classification of POP is categorized according to the affected compartment. Simply put, anterior compartment prolapse (cystocele) generally involves descent of the bladder toward the vaginal lumen, posterior prolapse (rectocele) involves the rectum compressing the posterior vaginal wall into the vagina, and apical prolapse is associated with descent of the uterus (uterine procidentia) and/or the bowel (enterocele) at the top of the vagina. Several grading systems exist to quantify the severity of POP and are discussed later in this chapter and illustrated in Fig. 112.1.

Regarding UI specifically, the substantiation of a proper diagnosis requires direct observation of urinary leakage by the clinician (Kobashi et al., 2017; Nitti and Blaivas, 2007). It is the belief of many experts that no patient should undergo invasive or irreversible therapies without definitive establishment of the cause of their incontinence and demonstration of leakage in the specific case of SUI. Complete and extensive evaluation can facilitate accurate diagnosis of

PFDs to promote optimal treatment planning and counseling of patients. Not only is it imperative that patients be aware of the risks, benefits, and alternatives of their treatment, but it has been shown that patients who understand their condition and the rationale behind their treatment have better outcomes (Kobashi et al., 2017).

Key Points

- PFDs are a prevalent worldwide health concern.
- Careful history and physical with objective demonstration of incontinence are integral in the proper evaluation of patient with PFDs.
- Supplementary evaluation including urinaylsis, postvoid residual, urodynamics, endoscopy, and radiologic imaging can be helpful in facilitating a complete and accurate diagnosis.
- A variety of surgical and nonsurgical options are available for treatment of urinary incontinence and pelvic organ prolapse.
- The degree of bother the symptoms of the PFDs are causing should be taken into account when considering treatment.

History

A careful history should always be obtained from the patient. However, several studies have indicated that patient history alone is not completely accurate as the sole determinant of incontinence type (Jensen et al., 1994; Summitt et al., 1992). In a systematic review of 3545 patients, women with a clinical history of SUI had 73% chance of having SUI, whereas women with no clinical history had a 16% chance of having SUI (Martin et al., 2006b). Bates et al. (1973) are credited with the dictum, “The bladder is an unreliable witness,” which has been corroborated by many investigators in various forms. Accordingly, all available information, including that which is obtained by supplementary examinations, should be integrated into the diagnosis.

History of Present Illness

A thorough history is imperative in the evaluation of incontinence. Several queries should be included in a continence and pelvic floor history to best portray the patient's symptoms (Holroyd-Leduc et al., 2008). ***The incontinence should first be characterized subjectively.*** Does the leakage occur: With physical activity? With a sense of urgency? Without sensory awareness? If the nature of the incontinence is mixed, does one component cause more bother or occur more frequently than the other? ***Second, the leakage should be quantified if possible.*** Appraisal of the degree of leakage before therapy can be helpful during postoperative assessment of treatment impact. For the purposes of routine outpatient assessment, this quantification can be achieved based on the number of pads used per day or the frequency of clothing changes resulting from urinary leakage. In the setting of research or an academic practice, more stringent and objective measures such as pad weight testing are often used (see “Supplemental Evaluation” later in this chapter). ***Third, the voiding pattern should be defined.*** What is the frequency of urination during the day? During the night? Are there any obstructive symptoms? Does the patient have to wait for the stream to start (hesitancy)? Does the patient feel as though he or she empties the bladder completely? Is the stream strong, or does it “trickle”? Does the stream fluctuate during the void (intermittency)? Is it necessary to push or strain or change posture to void or empty the bladder? ***Fourth, establishment of the duration of symptoms and any inciting events that contributed to the onset of leakage is important.*** Did the leakage follow a pregnancy or a vaginal delivery? How long ago? Did the leakage start after a strain, a fall, or trauma? Has the patient undergone pelvic or back surgery? In males, has there been any prostate or urethral surgery for benign or malignant disease? Has there been any lower urinary tract instrumentation? Are there any accompanying neurologic symptoms, such as numbness or tingling in the extremities, blurry/double vision, balance or coordination changes, or tremor? **It is helpful to determine the impact that the leakage has on the patient's daily life and activities.** Does the incontinence limit the individual's activity? Has the individual changed his or her lifestyle because of the threat of leakage? Questionnaires can be helpful adjuncts when assessing the impact the condition is having on an individual's QoL and the degree of bother the symptoms are causing him or her. **Finally, the American Urological Assocation (AUA) guidelines emphasize the importance of establishing patient expectation of treatment and an understanding of the balance between the benefits and risks/burden of available treatment options** (Kobashi et al., 2017).

Regarding pelvic prolapse specifically, important questions focus on

whether or not the patient is aware of any prolapse and what, if any, symptomatology and bother the prolapse may be causing. Does the patient feel that anything is falling down out of place in the vagina? Does she need to reduce the prolapse for comfort? Or to empty her bladder completely? Or to facilitate evacuation of her bowels? Patients with pelvic prolapse should also be assessed for presence of SUI given the high co-occurrence of these conditions (Roovers et al., 2007).

Past Medical and Surgical History

Past medical and surgical histories are vital to the assessment of incontinence insofar as medical conditions and surgeries can affect urinary tract function. Childhood and adult urologic history should be obtained, as should a neurologic history. **Neurologic conditions** such as Parkinson disease, multiple sclerosis, stroke, spinal cord injury, back surgery, and myelodysplasia can have a considerable impact on lower urinary tract (LUT) function. **Medical diagnoses**, such as diabetes mellitus and dementia, can affect continence. Similarly, a history of **radiation therapy** or neurologic or urologic **trauma** can affect LUT function, specifically with regard to outlet resistance and/or bladder contractility, stability, and compliance. Although outlet resistance may be compromised by trauma or LUT surgery, urethral strictures related to trauma or neurologic dysfunction that abnormally increase outlet resistance during voiding can cause obstruction and secondary symptoms related to the obstruction.

In women, the **gynecologic and obstetric history,** including gravity, parity, and hormonal status, is important. Determination of whether the patient is pre-, peri-, or postmenopausal, and whether or not she has used any exogenous hormones such as oral contraceptives or local or systemic hormone replacement therapy can be helpful in her overall assessment. As mentioned earlier, although beneficial effects of local hormone replacement therapy are well-established, there have been reports that exogenous systemic hormone therapy can actually increase the risk for SUI (Cody et al., 2012; Townsend et al., 2009; Waetjen et al., 2011).

Clearly, **previous pelvic surgery** can affect LUT function. Anti-incontinence surgery, POP repair, and hysterectomy can contribute to a variety of urinary symptoms in women. Similarly, a history of prostate surgery can give rise to voiding or leakage complaints in men. Abdominoperineal resection can result in neurologic injury that can affect the function of either the bladder or the sphincter (Petrelli et al., 1993), and back surgery can cause a variety of symptoms dependent on the level involved.

Medications

An accurate assessment of mediations is critical, particularly in the elderly patient population in whom polypharmacy is common. Many agents can affect urine production, LUT function, and mental status, all of which can have an impact on continence. Special attention should be focused on agents that can affect bladder/sphincteric function. Table 112.3 categorizes some commonly used classes of medications by mechanism of action and potential effect on the LUT.

TABLE 112.3

Pharmacologic Agents That Can Affect the Lower Urinary Tract

PHARMACOLOGIC EFFECTS	COMMON AGENTS	POTENTIAL EFFECTS ON URINARY TRACT
Sympathomimetics	Ephedrine, methylphenidate, cocaine, amohetamine	Can increase outlet resistance and exacerbate obstructive symptoms/overactive bladder symptoms
		Can decrease detrusor contractility and precipitate retention
Sympatholytics	Terazosin, doxazosin, tamsulosin, alfuzosin, silodosin	Can decrease outlet resistance and exacerbate stress incontinence
Anticholinergics	Oxybutynin, fesoteridine, solifenacin, trospium, darifenacin	Can contribute to urinary retention, particularly in patients with outlet obstruction
Diuretics	Furosemide, thiazides, spironolactone, triamterene, bumetanide	Do not affect bladder directly, but because of increased urine production, can aggravate incontinence problems

Other

As **genetics** can influence connective tissue integrity, it stands to reason that there may be a potential hereditary role in continence and POP (Richter et al., 2015; Twiss et al., 2007). Accordingly, inquiry about family history of POP may be helpful. Additionally, a thorough review of systems may reveal symptoms that suggest other conditions that could impact pelvic floor function.

Male incontinence, also a very prevalent health issue, should be assessed in much the same way as female incontinence, although specific consideration should be given to the impact of the anatomy specific to the male. **Benign prostatic hyperplasia**, the evaluation of which is covered in detail in Chapter 145, can cause secondary urgency and urgency incontinence in addition to more "typical" obstructive symptoms, such as a decreased force of stream, urinary hesitancy, intermittency, and incomplete bladder emptying. **Prostate surgery for benign or malignant disease** can contribute to SUI. With this in mind, full assessment of male LUTS should be performed to facilitate proper treatment planning.

Key Points

- A thorough history is essential in the diagnostic evaluation of patients with PFDs.
- Queries specific to the character, severity, duration, and quantity of incontinence and other symptoms related to pelvic floor function should be performed.
- Attention should be paid to the impact of PFD symptoms on QoL.
- When appropriate, the clinician should present questions specific to the female with potential pelvic organ prolapse and the male with potential prostate issues.
- Queries regarding past medical and surgical history, obstetric and gynecologic history, radiation therapy, trauma, and medications may provide important information.

Physical Examination

The general appearance of a patient, including details such as age, gait, stature, and fragility, can provide important information regarding performance status, neurologic status, and other factors that may direct proper treatment planning. Similarly, an abdominal examination evaluating incisions, hernias, organomegaly, bladder distension, and body habitus is important, particularly if abdominal surgery may be considered.

Frailty assessment of patients with PFDs, particularly if considering surgical intervention, is of utmost importance as frailty has been shown to affect surgical outcomes (Makary et al., 2010). The 5th International Consultation on Incontinence (ICI) presented a treatment algorithm that specifically addresses the management of the frail patient with UI (Wagg et al., 2015). Tools such as the "Timed up and Go" and the "FRAIL scale" have been developed for the assessment of frailty and can be useful in the evaluation of patients with PFDs (Morley et al., 2012; Pangilinan et al., 2017).

Per Medicare coding guidelines (Centers for Medicare and Medicaid Services, 1997), **a comprehensive female pelvic examination includes all bullet items listed in Table 112.4.** The **external genitalia** should be evaluated with regard to general appearance, **estrogen status,** lesions, and labial size and adhesions. Estrogen status can be evaluated based on the presence or absence of a urethral caruncle, urethral prolapse, and/or labial adhesions, all of which may indicate estrogen deficiency. Similarly, attention to the overall tissue appearance and color is important. Hormonally deficient vaginal tissue has a pale, flat, dry appearance with no rugae, as opposed to the healthy, pink rugaeted tissue of well-estrogenized tissue.

TABLE 112.4

Components of a Focused Pelvic Examination

Genitourinary Female
Pelvic examination (with or without specimen collection for smears and cultures), including: • Examination of external genitalia (e.g., general appearance, hair distribution, lesions) and vagina (e.g., general appearance, estrogen effect, discharge, lesions, pelvic support, cystocele, rectocele)

- Examination of urethra (e.g., masses, tenderness, scarring) Examination of bladder (e.g., fullness, masses, tenderness)
- Cervix (e.g., general appearance, lesions, discharge)
- Uterus (e.g., size, contour, position, mobility, tenderness, consistency, descent or support)
- Adnexa/parametria (e.g., masses, tenderness, organomegaly, nodularity)
- Anus and perineum

Note: At the time of this writing, all bullet points listed above are required to be considered a complete female genitourinary examination. However, other organ systems/body areas not limited to the genitourinary system may be included in a report to accomplish the requirements of various levels of examination.

From CMS 97 guidelines for focused female pelvic examination. Documentation Guidelines for Evaluation and Management (E/M) Services, jointly approved by the American Medical Association and HCFA with revisions November, 1997.

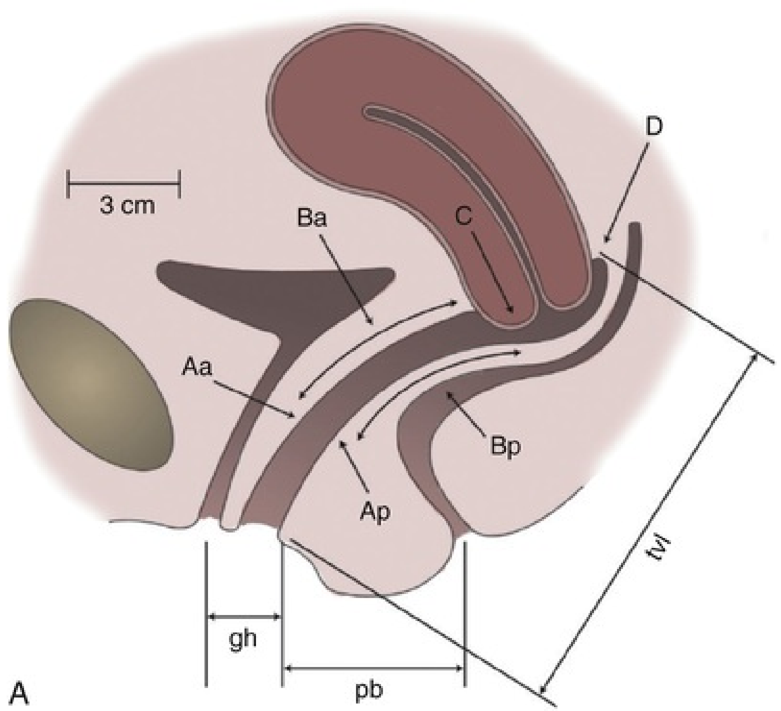
Consistent with prior iterations, the most recent AUA guidelines for surgical treatment of SUI recommend the objective demonstration of SUI (Kobashi et al., 2017). The most common methodology to document SUI on examination is the supine cough stress test, though this can also be performed in the standing position, particularly if SUI is not demonstrated in the recumbent position. A recent study evaluating the cough stress test showed that a bladder filled to one-half normal capacity (~200 mL) had a 90% specificity and 84% sensitivity (Henderson et al., 2018).

Urethral position and mobility should be assessed at rest and with straining and coughing. The **Q-tip test** was developed to objectify the evaluation of urethral mobility (Bergman and Bhatia, 1987; Walters and Diaz, 1987). The Q-tip is inserted into bladder through the urethra and the angle that the Q-tip moves from horizontal to its final position with straining is measured. Hypermobility is defined as a Q-tip angle of >30 degrees from horizontal. Insertion of the Q-tip can be uncomfortable, and this discomfort can be mitigated with the use of intraurethral lidocaine jelly.

DeLancey described the connective tissue support of the pelvis and the pelvic viscera in three levels. Levels I, II, and III represent the proximal, middle, and distal vaginal support, respectively, in this classification system that is utilized worldwide. Level I support depends on the uterosacral and cardinal ligaments and supports the vaginal vault; level II support applies to the mid-vagina and involves the attachment of the anterior and posterior endopelvic fascia to the lateral pelvic side walls; and level III support constitutes the fusion of the endopelvic fascia to the pubic symphysis and perineal body (DeLancey, 1992). **Assessment of prolapse should ideally be performed in both the lithotomy**

and standing positions, the latter facilitated by having the patient stand with one foot elevated on a short stool. Each compartment—the anterior, posterior, and apical (uterus/cervix or vaginal cuff) —should be evaluated methodically and the perineal body assessed for laxity. A complete systematic examination is performed using two posterior blades of a split Grave's speculum with and without straining. First, one blade is used to retract the posterior wall to facilitate anterior compartment examination. The blade is then repositioned to retract anteriorly for examination of the posterior compartment. Finally, both blades are inserted simultaneously, one anteriorly and one posteriorly, to isolate the vaginal apex and facilitate examination of the cervical or cuff support. The posterior blade is slowly withdrawn to examine the posterior wall. Next, with the posterior blade in place, the patient is asked to strain. Foreshortening of the posterior wall results in expulsion of the blade and suggests a compromise in the level I support (cardinal-uterosacral ligament complex) of the vault (DeLancey, 1992); if the blade remains in place, this could represent an isolated rectocele or enterocele without vault prolapse. Evaluation for occult SUI should be performed with the anterior wall supported. SUI can be masked if significant prolapse “kinks” the urethra and outlet.

Several classification systems are used to quantify POP, the most widely used of which are the **Baden-Walker classification** (Baden et al., 1968) **and the Pelvic Organ Prolapse-Quantification system, known as the “POP-Q”** (Bump et al., 1996). The two systems are juxtaposed in Fig. 112.1. **In the POP-Q system, which was created in an effort to provide objectivity to POP quantification, nine specific points of measurement are obtained in relation to the hymenal ring as illustrated in Fig. 112.2.** Six vaginal points labeled Aa, Ba, C, D, Ap, and Bp are measured during the Valsalva maneuver. Points above the hymen are considered negative, and points below the hymen are positive. The genital hiatus (gh) represents the size of the vaginal opening, and the perineal body (pb) represents the distance between the vagina and the anus. The total vaginal length (tvl) is measured by reducing the prolapse and measuring the depth of the vagina. Table 112.5 contains the **POP-Q staging criteria,** a simplified presentation of the POP-Q system, and Fig. 112.3 illustrates an example of the application of the system.



Point	Description	Range of values
Aa	Anterior vaginal wall 3 cm proximal to the hymen	–3 cm to +3 cm
Ba	Most distal position of remaining upper anterior vaginal wall	–3 cm to +tvl
C	Most distal edge of cervix or vaginal cuff scar	–
D	Posterior fornix (N/A if posthysterectomy)	–
Ap	Posterior vaginal wall 3 cm proximal to the hymen	–3 cm to +3 cm
Bp	Most distal position of remaining upper posterior vaginal wall	–3 cm to +tvl
gh (genital hiatus)	Measured from middle of external urethral meatus to posterior midline hymen	–
pb (perineal body)	Measured from posterior margin of gh to middle of anal opening	–
tvl (total vaginal length)	Depth of vagina when point D or C is reduced to normal position	–

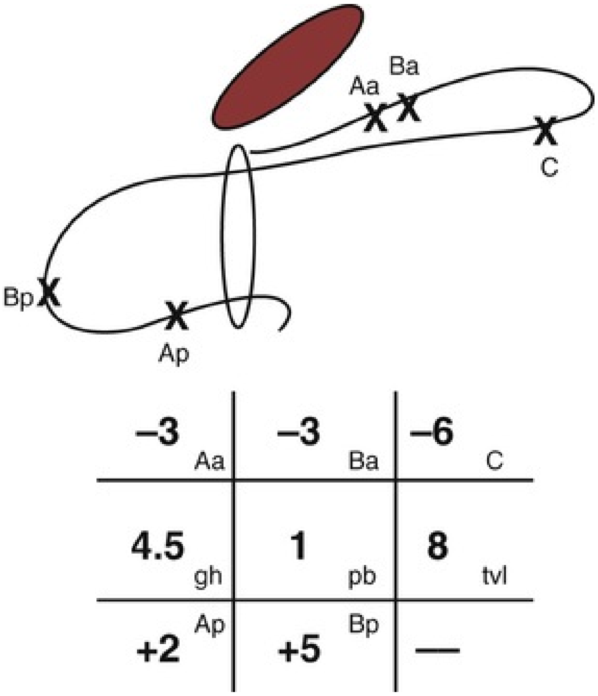
B

FIG. 112.2 (A) Landmarks for the POP-Q system. (B) POP-Q points of reference. (A, From Bump RC, Mattiasson A, Bo K, et al. The standardization of terminology of female pelvic organ prolapse and pelvic floor dysfunction. *Am J Obstet Gynecol* 175:10–7, 1996.)

TABLE 112.5

POP-Q Staging Criteria

STAGE	CRITERIA
0	Aa, Ap, Ba, Bp at –3 cm and C or D ≤ – (tvl – 2) cm
I	Stage 0 criteria not met and leading edge < –1 cm
II	Leading edge ≥ –1 cm but ≤ +1 cm
III	Leading edge > +1 cm but < + (tvl – 2) cm
IV	Leading edge ≥ + (tvl – 2) cm



–3 Aa	–3 Ba	–6 C
4.5 gh	1 pb	8 tvl
+2 Ap	+5 Bp	—

FIG. 112.3 Line drawing example of posterior support defect. The anterior compartment is well supported. Bp is the leading point of the prolapse relative to the reference point of the hymen. At +5, Bp is 5 cm beyond the hymen. Point *C* designates the cuff position. Taking into consideration a total vaginal length (tvl) of 8 cm, the cuff has descended 2 cm. (From Bump RC, Mattiasson A, Bo K, et al. The standardization of terminology of female pelvic organ prolapse and pelvic floor dysfunction. *Am J Obstet Gynecol* 175:10–17, 1996.)

With the use of mesh in the surgical approach to PFDs, mesh-related complications have become more commonly encountered. Patients with these complications often present with symptoms, however, many can be asymptomatic. Consequently, patients who have undergone prior pelvic floor surgery with mesh that present with pain or voiding symptoms of any type should undergo a thorough history and examination. Pelvic examination should evaluate for the presence, location, and size of any mesh extrusion. Presence of tenderness, even in the absence of mesh exposure, should be documented. In 2011 IUGA and ICS developed joint terminology and classification of complications related directly to the use of prosthesis and grafts in female pelvic surgery (Haylen et al., 2011). Providers could refer to these classification when evaluating complications related to mesh used in pelvic floor surgery.

A **neurologic examination** is important in any patient with a known or suspected neurologic condition. Attention to the patient's gait, speech, cognitive status, facial symmetry, sensation in the lower extremities and perineal and perianal regions, lower extremity motor strength, and vaginal and pelvic floor strength can provide helpful information. Mobility and cognitive status can play a role in urinary continence insofar as both can affect a patient's ability to reach the facilities in a timely fashion. The **bulbocavernosus reflex (BCR)**, which is representative of sacral nerve root levels 2 to 4 (S2–S4), is present in 70% of normal females and 100% of normal males. The BCR is considered positive when squeezing of the glans penis or clitoris results in anal and pelvic floor contraction that can be detected visually or by rectal exam. Alternatively, applying traction to an indwelling Foley catheter to pull the balloon against bladder neck should also precipitate a BCR.

A **digital rectal examination (DRE)** is important in men to assess the prostate for size, nodularity, and tenderness. In the female, the DRE can facilitate assessment of the rectovaginal septum. Demonstration of a rectocele can be facilitated by applying anterior pressure with a finger placed in the rectum. Anal sphincter tone, which is a reflection of the function at S2–S4, is particularly important in neurologic patients with PFDs. Patients are asked to voluntarily tighten the pelvic floor as if attempting to stop the flow of urine midstream. Laxity in the rectal sphincter tone may suggest a possible neurologic defect, but one must also consider the possibility that it may be caused by a patient's lack of understanding regarding how to voluntarily control the specific muscle groups necessary for contraction.

In men, genitourinary examination as it pertains to voiding function should also include evaluation of the penis for meatal stenosis and, particularly in the post-prostatectomy patient, visible urinary leakage with coughing and straining. Examination for leakage is ideally performed with the patient in the standing position.

Key Points

- A properly performed physical examination is imperative in the evaluation of patients with PFDs.
- The Centers for Medicare and Medicaid Services require specific elements of both male and female genitourinary examination to meet coding guidelines (see Table 112.4).
- Assessment of POP should ideally be performed in both the supine and standing positions.
- Several classification and quantification systems are available for assessment of POP, and the most widely used systems (Baden-Walker and POP-Q) are illustrated in Figs. 112.1 and 112.2.
- A neurologic examination and rectal examination should be performed in appropriate patients to obtain complete clinical information important in the assessment of lower urinary tract and pelvic floor function.

Supplemental Evaluation

A variety of measures are available to supplement the history and physical examination in patients with PFDs. Instruments exist to quantify symptoms, their effects on QoL, and the degree of bother experienced by patients with PFDs. **Most experts concur that a urinalysis (UA) and postvoid residual (PVR) measurement should be considered in the majority of patients undergoing evaluation for incontinence. However, beyond this, there are no universally agreed-on standards regarding the roles of other studies, such as endoscopy, urodynamics (UDS), radiographic imaging, and various modalities of symptom quantification including voiding diaries, pad tests, and questionnaires** (Zimmern et al., 2010). In an effort to address this, the American Urological Association (AUA) and the Society of Female Pelvic Medicine and Reconstructive Surgery (SUFU) published guidelines based on the current literature (Gormley et al., 2012; Kobashi et al., 2017; Winters et al., 2012).

According to the guidelines, a urinalysis (UA) is part of the minimum proper evaluation of the overactive bladder (OAB) patient. Urine culture and PVR can be obtained at the discretion of the clinician. The guidelines state that UDS, cystoscopy, and renal ultrasonography should not be a part of the initial evaluation of the uncomplicated OAB patient (Gormley et al., 2012). For SUI, evaluation of the index patient who is considering treatment should include a UA and PVR assessment. UDS, pad tests, cystoscopy, and imaging can be considered (Kobashi et al., 2017) in specific situations such as those outlined in Table 112.6. In circumstances in which further investigation is considered, the value and accuracy (sensitivity and specificity) of the information provided by the given assessment method should be considered in relation to the cost and morbidity of the examination.

TABLE 112.6

Circumstances That Warrant Consideration of Supplemental Evaluation

- Inability to make definitive diagnosis based on symptoms and initial evaluation
- Inability to demonstrate stress urinary incontinence
- Known or suspected neurogenic lower urinary tract dysfunction
- Abnormal urinalysis, such as unexplained hematuria or pyuria

- Urgency-predominant mixed urinary incontinence
- Elevated post-void residual per clinician judgment
- High grade pelvic organ prolapse (POP-Q stage 3 or higher) if stress urinary incontinence not demonstrated with pelvic organ prolapse reduction
- Evidence of significant voiding dysfunction

Symptom Quantification Instruments

Voiding Diaries

Instruments such as voiding diaries, questionnaires, and pad tests, have been developed to aid in the quantification of urinary loss, both symptomatically and volumetrically. **Voiding diaries can provide valuable diagnostic and therapeutic information. The use of diaries often helps patients realize their pattern of urination and is more accurate than recall** (Larsson et al., 1984; McCormack et al., 1992; Siltberg et al., 1997)**. Furthermore, the diary can provide patients with insights into behaviors that can be altered to decrease urinary frequency** (Burgio, 2004)**. Despite its common use, the first validated voiding diary was only recently developed by the ICS in 2014 with the creation of a 3-day voiding diary called the ICIQ bladder diary** (Bright et al., 2014).

Several studies have demonstrated the adjunctive role that diaries can have in the diagnosis and management of incontinence. Diaries can be an adjunct to a routine subjective history as it has been demonstrated that patient recall is not often as accurate as a formal voiding diary in ascertaining urinary frequency. In a retrospective review of 601 patients who underwent sling surgery and completed bladder diaries, only 47% were accurate about their daytime frequency; 51% overestimated their diurnal frequency, and this overestimation was exaggerated in those who reported voiding more than 10 times per day (Stav et al., 2009). Overestimation rates were similar between patients with and without overactive bladder (OAB) symptoms. Interestingly, 93% of women in this study were accurate about their nighttime frequency. In another study of women with UI, it was noted that the overestimation of incontinence episode frequency occurred more often in those patients who were more bothered by their incontinence. Conversely, Ku et al. (2004) found a poor correlation between subjective nocturnal frequency and that noted by 164 patients on their frequency volume charts. Wyman similarly showed a higher correlation of diary-reported frequency in the daytime versus the night (Wyman et al., 1988).

Martin et al. (2006) performed a meta-analysis of 121 in 6099 papers that compared two or more diagnostic techniques for incontinence and showed that diaries are most cost-effective when used in conjunction with history, particularly in patients undergoing treatment for detrusor overactivity (DO). It should be noted, however, that diaries should not substitute for more formal studies in select patients. One study that retrospectively assessed the Larsson frequency/volume chart as compared with the cystometrogram in 216 patients demonstrated the sensitivity and specificity of the chart with regard to DO to be 52% and 70%, respectively, and with regard to SUI, 66% and 65%, respectively (Tincello and Richmond, 1998). For daily clinical practice, 24-hour diaries should suffice to obtain valuable clinical information regarding LUT function; in academic studies, longer diaries may be requested, but this should be balanced with the well-established knowledge that the more complex a given instrument is (i.e., the more data requested), the lower patient compliance will be in completing it (Groutz et al., 2000). In the current digital era, traditional paper voiding diaries are being replaced by electronic voiding diaries. Studies have demonstrated the benefit of the latter in preventing backfill and in a potential increase in patient compliance while maintaining good test reliability (Sussman et al., 2016).

Questionnaires and Quality of Life Instruments

Questionnaires can provide a helpful complement to the patient history and patient reported outcomes (PROs). A plethora of instruments to evaluate symptoms, degree of bother, and QoL in patients with incontinence and PFDs have been developed in an effort to provide optimal assessment of outcomes and to eliminate the confounding issue of physician bias; many have been validated. Table 112.7 contains validated questionnaires highly recommended by the ICI. One such instrument, the modular ICI questionnaire (ICIQ), was developed by the ICI in an effort to collaboratively develop a universally applicable instrument that could be utilized to assess pelvic floor function in both clinical practice and research settings (Abrams et al., 2005). To allow it to be used globally, the ICIQ has been translated in 38 languages. The short form of the ICIQ (ICIQ-SF) has been shown to correlate nicely with both the 1-hour (Franco et al., 2008) and 24-hour (Karantanis et al., 2004) pad test for evaluation of the severity of SUI. Another comparison of the 24-hour pad test, the ICIQ-SF, the International Prostate Symptom Score (IPSS), and the postoperative Patient Global

Impression of Improvement (PGI-I) score in 26 men after perineal sling placement confirmed the construct validity of these instruments (Twiss et al., 2007). There was a strong correlation demonstrated between the ICIQ-SF and PGI-I scores and the percentage reduction in 24-hour pad weight. At the time of this writing, available ICI modules include the ICIQ-MLUTS (male LUTS), ICIQ-FLUTS (female LUTS), ICIQ-SF, ICIQ-OAB, ICIQ-VS (vaginal symptoms), ICIQ-N, and the recently developed ICIQ-Bladder diary. Additional modules covering QoL, sexual function, pediatric LUTS, neurogenic LUTS, and bowel function are available or are in development and are or will be available through the ICI (Abrams et al., 2017).

TABLE 112.7

Instruments Highly Recommended by the International Consultation on Incontinence for Urinary Incontinence, Overactive Bladder, Lower Urinary Tract Symptoms, and Pelvic Organ Prolapse Patient Reported Outcomes

QUESTIONNAIRE	POPULATION	PURPOSE OF INSTRUMENT
Health-Related Quality Of Life		
BFLUTS (Bristol Female Lower Urinary Tract Symptoms Questionnaire) aka ICIQ-FLUTS (Jackson et al., 1996)	Women, incontinence	To assess female LUTS, particularly incontinence; measure impact on QoL; and evaluate treatment outcome
DAN-PSS-1 (Danish Prostatic Symptom Score) (Hansen et al., 1995)	Men, BPH	To evaluate males with LUTS suggestive of uncomplicated BPH
ICIQ-UI-SF (ICIQ Urinary Incontinence Short Form) (Avery et al., 2004)	Men and women, urinary symptoms	To assess symptoms and impact of urinary incontinence in clinical practice and research
ICSmale (ICIQ-MLUTS) (Donovan et al., 1996)	Men with LUTS and possible BPH	To provide evaluation of occurrence and bothersomeness of LUTS and their impact on the lives of men with BPH
ICS-LUTSqoL (Donovan et al., 1997)	Men with LUTS and possible BPH	To assess impact of LUTS on the lives of men with LUTS
IIQ (Incontinence Impact Questionnaire (Wyman et al., 1987)	Women, UUI, SUI	To assess impact of incontinence on HRQOL, primarily in patients with SUI

IIQ-7 (IIQ-short form) (Uebersax et al., 1995)	Women, UUI, SUI	To assess impact of urinary incontinence on HRQOL
I-QoL (ICIQ-UIqol) (Urinary incontinence-specific QoL instrument) (Wagner et al., 1996)	Women, UUI	To assess QoL of women with urinary incontinence
KHQ (King's Health Questionnaire) (ICIQ-LUTSqol) (Kelleher et al., 1997)	Men and women, OAB	To assess the impact of LUTS on HRQOL
N-QoL (ICIQ-Nqol; Nocturia QoL) (Abraham et al., 2004)	Men and women	To assess the impact of nocturia on QoL
OABq-SF (Coyne et al., 2002)	Men and women, OAB	Shortened version of OAB-q to evaluate both continence and incontinence symptoms of OAB and their impact on QoL
OAB-q (ICIQ-OABqol) (Coyne et al., 2002)	Men and women with OAB wet and OAB dry	To evaluate both OAB-wet and OAB-dry symptoms and their impact on HRQOL
PRAFAB (Protection, Amount Frequency, Adjustment, Body image) (Hendriks et al., 2007)	Women, UUI	To evaluate treatment effects for UUI in women
UISS (Urinary incontinence severity score) (Stach-Lempinen et al., 2001)	Women, UUI	To assess symptom severity and impact of urinary incontinence on everyday life
Urolife (BPH-QoL9) (Lukacs et al., 1997)	Men, BPH	To assess the impact of BPH and its treatment on the QoL of patients
Screeners		
B-SAQ (Bladder-Self-Assessment Questionnaire) (Basra et al., 2007)	Women	Screening tool for the presence of bothersome LUTS in women
LUSQ (Leicester Urinary Symptom Questionnaire) (Shaw et al., 2002)	Men and women, LUTS	Condition-specific screener of storage LUTS (urgency, frequency, nocturia, and incontinence)
OAB-SS (OAB Symptom Score) (Blaivas et al., 2007)	Men and women, LUTS with and without OAB	7-item tool to measure overall symptom severity due to the four index symptoms of OAB
OAB-V8 (OAB Awareness Tool) (Coyne et al., 2005)	Men and women, OAB	8-item screening tool for use in primary care setting to identify patients who may have OAB
QUID (Questionnaire for Urinary Incontinence Diagnosis)	Women, UUI and SUI	6-item tool to diagnose SUI and UUI

(Bradley et al., 2005)		
ICIQ Bladder diary (Bright et al., 2014)	Men and women, LUTS	3-day diary assessing volume, frequency, intake and incontinence episodes
Symptom bother		
PPBC (Patient perception of bladder condition) (Coyne et al., 2006)	Men and women	To assess patients' subjective impression of their current urinary problems. Developed as a global assessment of bladder condition.
UDI-6 (Urogenital Distress Inventory-6/short form) (Uebersax et al., 1995)	Women	To assess LUTS bother, including incontinence, in women
Urgency		
IUSS (Indevus Urgency Severity) (Nixon et al., 2005)	OAB with urgency incontinence, men and women	To quantify the level of urgency associated with each toilet void as measured during standard voiding diaries
POP symptoms and QoL		
PFDI (Pelvic floor distress inventory) (Barber et al., 2001)	Women	To quantify the symptoms caused by pelvic prolapse
PFIQ (Pelvic floor impact questionnaire) (Barber et al., 2001)	Women	To quantify the effects of pelvic prolapse on QoL
Sexual matters		
ICIQ-MLUTSsex; ICIQ-Bsex (McKown et al., 2010)	Men	Assessment of male sexual bother related to LUTS and bowel symptoms
ICIQ-FLUTSsex; ICIQ-Bsex	Women	Assessment of female sexual bother related to LUTS and bowel symptoms

BPH, Benign prostatic hypertrophy; *HRQOL,* health-related QoL; *ICIQ,* International Consultation on Incontinence Questionnaire; *ICS,* International Continence Society; *LUTS,* lower urinary tract symptoms; *MLUTS/FLUTS,* male/female lower urinary tract symptoms; *OAB,* overactive bladder; *PRO,* patient recorded outcomes; *QoL,* quality of life; *SF,* short form; *SUI,* stress urinary incontinence; *UUI,* urgency urinary incontinence.

A study examining the incontinence-related and non–incontinence-related pelvic floor symptoms evaluated by two widely utilized symptom tools, the Urogenital Distress Inventory (UDI)-6 and the ICIQ-UI, demonstrated that both symptom questionnaires were sound and correlated with each other and independently with the QoL scores, as measured by the IIQ-7 and IQOL (van de Vaart et al., 2010). This study also uncovered the interesting finding that the delay in time to consultation with a physician was associated with greater bother, emphasizing the importance of heightened awareness of PFDs in the female patient population.

In Martin's meta-analysis, two studies showed a high sensitivity (0.82 to 0.92) of question 3 in the Urogenital Distress Inventory for SUI; the specificity was 0.51 to 0.69 (Martin et al., 2006). In this study, history alone had a pooled sensitivity of 0.92 (95% CI) and a specificity of 0.56 for the diagnosis of SUI and a sensitivity of 0.61 and specificity of 0.87 for the diagnosis of DO. **It should be borne in mind, however, that for higher risk interventions such as surgery, the most accurate testing available remains multichannel UDS studies.**

Pad Tests

Pad tests are generally used for academic purposes. **The ICS recommends both a 3-day bladder diary and pad weight test as proper measures for symptom quantification in incontinence research** (Lose et al., 2001). However, although pad tests can be helpful in quantifying leakage, they are tedious and cumbersome for patients. Moreover, they do not provide information that is necessary for daily routine clinical practice. **The 5th ICI Committee on initial assessment did not recommend pad tests as part of the initial evaluation in the incontinent patient** (Abrams et al, 2013)**. From an *academic* standpoint, however, many investigators advocate pad tests in clinical trials, as pad tests can provide objective, precise information for assessment of actual volume of urine lost over an established period.**

According to the 3rd ICI, greater than 1.3 g of urine loss is considered a "positive" 24-hour pad test (Abrams et al., 2005a)**. Others consider up to 8 g of urine loss in 24 hours to be normal** (Lose et al., 1989). This variability poses a potential limitation on the utility of the pad test, however, many investigators utilize the test for research purposes. Vaginal secretions should also be taken into consideration, although the volume attributable to normal vaginal secretions may be as low as 0.3 g in 24 hours (Karantanis et al., 2003). O'Sullivan et al. (2004) evaluated 110 women with incontinence with two 1-hour pad tests and 7 consecutive days of 24-hour pad tests. The severity of the leakage was analyzed in relation to UDS parameters, age, parity, and pelvic floor muscle strength, showing increased severity with increasing age and parity and in those women who demonstrated DO. The authors proposed that a 24-hour loss of 1.3 to 20 g, 21 to 74 g, and greater than 75 g to signify “mild,” “moderate,” and “severe” incontinence, respectively. Another study of 144 randomly selected Danish women who underwent 24-hour pad testing revealed a similar loss of urine in the self-reported continent and incontinent groups or 3.1 and 3.3 g, respectively (Ryhammer et al., 1998).

It is generally agreed that the 24-hour pad test is a clinically more useful tool than the 1-hour pad test (Lose et al., 1989; Matharu et al., 2004); in fact, the test-retest reliability and the predictive value of the 1-hour test in the diagnosis of female incontinence has been shown to be poor (Constantini et al., 2008; Lose et al., 1986, 1988; Simons et al., 2001). Others have advocated the opposite extreme, suggesting that a 20-minute pad test with a standardized bladder volume of 250 cc instilled into the bladder via catheterization had superior sensitivity as compared with the 1-hour test conducted via the ICS standardized method of pad testing (Wu et al., 2006). The ICS method, described in 1988, requires the patient to drink 500 mL of sodium-free liquid in 15 minutes followed by a 30-minute resting period before proceeding with the recommended physical activity (Abrams et al., 1988). One potential concern about this method is the lack of standardization of bladder volume.

Parenthetically, pad use per day (PPD) obtained via patient history is a measure frequently used to quantify urine loss, but one study demonstrated that this is an unreliable measure of incontinence (Dylewski et al., 2007). In a retrospective chart review of 145 males and 116 females who underwent artificial urinary sphincter placement and sling surgery, respectively, and who had completed a self-reported pad-use query, the patients were asked to bring three pads into their clinic visit: one dry “reference” pad and the incontinence pads used for the 24-hour periods preceding and including the day of their visit. The pads were quantified and weighed to determine the grams of urine per pad (GPP). All patients also underwent a 24-hour pad weight test. Only a very weak correlation was found between reported pad usage and the 24-hour pad weight, with pad usage measuring only 38% of the variability of incontinence volume. Additionally, although the PPD decreased, the GPP increased with increasing age.

Dye Testing

Dye testing can be helpful to verify that the leakage represents urine versus another fluid such as vaginal discharge or peritoneal fluid and to substantiate the diagnosis of urinary tract fistulae. **Oral phenazopyridine** 100 mg or 200 mg three times a day colors the urine orange, and this simple test can confirm that the leaking fluid is indeed urine. Diagnosis of a vesicovaginal or urethrovaginal fistula can be supported by blue or orange staining of an intravaginal tampon after **intravesical instillation of methylene blue or pyridium dissolved in sterile water or saline.** In the case of a suspected *uretero*vaginal fistula, **intravesical methylene blue with concurrent oral pyridium** can elucidate the fistula location based on the staining pattern on the vaginal tampon. Orange staining suggests a ureteral communication, and blue staining connotes a bladder communication (Raghavaiah, 1974). The clinician must keep in mind that simultaneous vesicovaginal and ureterovaginal fistulae can occur.

Key Points

- It has been demonstrated that patient subjective history alone often does not reflect an accurate or complete picture of their symptomatology complex.
- Several instruments designed to facilitate symptom quantification have been developed and include tools such as voiding diaries, symptom and QoL questionnaires, and pad tests.
- Voiding diaries can be both diagnostic and therapeutic, as they can provide patients with insights into behaviors that may be contributing to their voiding symptoms.
- Pad tests may be helpful, particularly in the academic setting, to quantify incontinence symptoms. Loss of up to 8 g of urine in 24 hours may be considered normal, although the ICI considers loss of greater than 1.3 g to be a positive 24-hour test.
- Validated questionnaires are available to assess symptoms and quality of life in patients with PFDs.

Urinalysis

It is generally agreed that urinalysis plays a fundamental role in the evaluation of the incontinent patient or the patient with lower urinary tract symptoms (LUTS) (Abrams et al., 2009). The urinalysis provides information such as the presence of hematuria, pyuria, glucosuria, or proteinuria that can be indicative of conditions that can cause *secondary* incontinence. As indicated by the screening dipstick analysis, a microanalysis and/or culture should be performed that may provide guidance regarding further testing or therapy for conditions related to or independent of urinary incontinence.

Postvoid Residual

The volume of urine left in the bladder after routine voiding is termed the *postvoid residual (PVR),* and some authors have suggested that PVR should be evaluated in all incontinent patients (Gormley, 2007; Tubaro, 2005). This simple test, which can be performed via in-and-out catheterization or using noninvasive transabdominal ultrasonography, evaluates the bladder's emptying ability and can be helpful in the diagnosis of overflow incontinence. **The 2017 AUA/SUFU SUI guidelines state that clinicians considering invasive therapy in patients with SUI should assess PVR to evaluate bladder emptying as patients with elevated PVRs preoperatively are at increased risk of developing voiding difficulties postoperatively** (Kobashi et al., 2017). It is important to establish baseline bladder emptying, particularly in stress-incontinent patients who may be considered for an anti-incontinence procedure or patients with urinary urgency who may be candidates for therapies aimed at decreasing bladder contractility.

A number of studies have demonstrated that ultrasonography is comparable to catheterization in evaluating the PVR, although **there are no officially established volumes that define normal or impaired emptying.** The Agency for Healthcare Policy and Research (AHCPR) suggests that a PVR less than 50 cc represents adequate emptying and a PVR greater than 200 cc represents inadequate emptying (US Department of Health and Human Services, 1992). The International Continence Society considers a PVR greater than 200 to 300 mL concerning (Asimakopoulos et al., 2016). There is no consensus recommendation regarding the significance of PVR between 50 and 200 cc. In one study, Gehrich et al. (2007) enrolled 96 healthy women who presented for a routine “well-woman” checkup. Exclusion criteria included urinary incontinence more than twice per week, urinary retention, neurologic disease, or symptomatic POP. The mean and median PVRs were 19 cc (0 to 145 cc) and 24+/– 29 cc. 15% had PVR greater than 50 cc, and 95% had PVR less than 100 cc. Another study compared PVR measurements obtained by three-dimensional bladder scan versus catheterization in 170 women who were undergoing evaluation for SUI but who had never undergone previous pelvic surgery (Tseng et al., 2008). 35.5% had PVR greater than 50 cc, and 15.9% had PVR greater than 100 cc. Ultrasonography offered a sensitivity of 64.7% and a specificity of 94.3% in detecting PVR greater than 100 cc. Although several studies support the accuracy of the bladder scan (Al-Shaikh et al., 2009), some suggest that certain sonographic devices may provide more accurate information than others (Ghani et al., 2008).

Cystoscopy

Endoscopic examination of the bladder is important as a means to evaluate for intravesical or intraurethral pathology that may be contributing to the patient's symptomatology. Bladder tumors, bladder stones, cystitis, and intravesical or intraurethral foreign bodies such as mesh or suture can contribute to irritative voiding symptoms, recurrent urinary tract infections (UTIs), and incontinence. Patients with a history of previous pelvic floor reconstructive surgery should be evaluated for eroded materials into the LUT. The ureteral orifices should be identified and evaluated for morphology, position, number, and efflux. The bladder mucosa is examined for trabeculation (which can be suggestive of bladder outlet obstruction [BOO] and/or detrusor overactivity) and estrogen status, and the urethra is assessed for foreign bodies, stricture, diverticulum or fistula, and position.

The role of preoperative cystourethroscopy has been addressed by few authors. Anger et al. (2007) analyzed Medicare claims data to assess the effects of preoperative cystoscopy and UDS studies on sling outcomes. The data of a random 5% sample of Medicare beneficiaries during an established 18-month period were used to assess the likelihood of undergoing postoperative studies in those who did and did not undergo the same studies preoperatively. Although patients who underwent preoperative cystoscopy were less likely to undergo postoperative cystoscopy (23.4% vs. 35.2%, $P < 0.0001$) or UDS (19.3% vs. 34.0%, $P < 0.0001$), there were no significant differences in complications or repeat incontinence procedures between groups. However, Cundiff and Bent (1996) reported that cystoscopy changed the diagnosis and management in 6/84 women (7%) who underwent both cystoscopy and UDS for evaluation of LUT dysfunction. Findings included transitional cell carcinoma, cystitis glandularis, intravesical suture, and a urethral diverticulum.

Although the use of routine cystoscopy is not advocated in the evaluation

of the “index” stress urinary incontinence patient, it should be considered in patients who present with urinary urgency, hematuria, or other irritative symptoms, particularly if they have undergone a previous anti-incontinence procedure, pelvic radiation, or pelvic prolapse repair (Kobashi et al., 2017).

Urodynamics

Similar to cystourethroscopy, the routine use of UDS is the subject of much discussion; however, one should or may consider UDS in patients who are considering invasive, potentially morbid or irreversible surgery, have failed previous pelvic floor reconstruction, or who have mixed incontinence, urinary urgency, or obstructive symptoms, as well as in patients who have elevated PVRs or neurologic disease. UDS is also useful to confirm or refute a diagnosis and can facilitate patient selection and counseling. The benefit of UDS in these situations is to establish baseline bladder capacity, compliance, sensation, stability, and sphincter function before further surgical or therapeutic manipulation. A comprehensive review of UDS is presented in Chapter 114.

LUT function can be simply categorized into storage and emptying. Each of these categories is affected by the bladder (detrusor) and the outlet. **Two main questions should be considered in the evaluation of the incontinent patient: (1) Is the problem at hand a storage issue, an emptying issue, or a combination of the two?** ***and*** **(2) Is the etiology of #1 caused by a detrusor issue, an outlet issue, or a combination of both?**

“Eyeball UDS” is a simple economically favorable alternative to full multichannel UDS that can be helpful in selected patients. The study can determine bladder sensation, compliance, stability, and capacity as well as outlet competence and PVR. After voiding, the patient is placed in the lithotomy position and a Foley catheter is placed and the PVR measured. A 60-mL catheter tip syringe with the barrel removed is placed into the end of the catheter. With the syringe held upright, the bladder is filled with sterile fluid through the syringe. The height of the meniscus above the bladder represents the intravesical pressure. The volumes at first sensation and first desire, normal desire, and strong desire to void are recorded. During the filling phase, the meniscus in the syringe is observed for a rise and fall that may represent bladder overactivity or a consistent gradual rise that suggests compromised detrusor compliance. The absence of the abdominal pressure (Pabd) channel limits the ability to accurately determine any abdominal contribution to a change in the water volume in the syringe. The catheter is removed, and a cough stress test is performed by observing the urethra for incontinence during coughing and straining.

Multichannel UDS offers an extensive evaluation of LUT function. The degree of accuracy provided by multichannel UDS is important in a variety of circumstances, including when conservative treatment methods fail; when the diagnosis is unclear or previous diagnostic procedures are inconclusive; in patients with clinical pictures complicated by radiation therapy, neurologic disease, or prior failed pelvic floor reconstruction or anti-incontinence surgery; or when patients describe symptoms that cannot be confirmed by the clinician. A complete UDS study evaluates the ***filling/storage phase*** by filling cystometrogram and the ***voiding/emptying phase*** by uroflowmetry.

Catheters are placed into the bladder and the rectum. The bladder catheter measures the actual pressure within the bladder, termed the vesical pressure (Pves). The rectal catheter measures the abdominal pressure (Pabd). The detrusor pressure (Pdet) is a calculated value (Pves – Pabd) that represents the pressure created by the detrusor independent of the influences of intra-abdominal pressure. During the filling phase, the Pdet is expected to remain low and stable to allow for low-pressure bladder filling. Poorly compliant bladders will show a gradual steady rise in the Pdet as the bladder volume increases. Detrusor overactivity is manifest by intermittent and unpredictable rises in the Pdet. During the voiding phase, the Pdet may rise as the urine flows. Many women void normally with virtually no rise in Pdet. High Pdet with low flow during voiding suggests BOO. Inability to produce a flow with no Pdet, particularly when accompanied by abdominal straining (represented by an undulant Pabd), may indicate an atonic or hypotonic detrusor.

When making the diagnosis of urodynamic SUI, urethral function should be assessed (Winters et al., 2012). Quantitative measurements such as the Valsalva leak point pressure (VLPP) or maximal urethral closure pressure (MUCP) can be used to guide treatment decisions in patients suspected of having SUI who do not demonstrate leakage with stress maneuvers; stress testing should be repeated with urethral catheter removed. In patients with high-grade POP without symptoms of SUI, stress testing should be performed with the POP reduced to evaluate for occult SUI.

Electromyogram (EMG) and fluoroscopic imaging (“videourodynamics,” VURDS) are helpful adjuncts to the UDS study in selected patients and are covered in detail in Chapter 114. EMG activity is reflective of the activity of the striated muscles of the urethral and anal sphincters and the perineal musculature and can be measured using either surface electrodes or needle electrodes. Although the latter provides more accurate readings, the discomfort caused to the patient and the expertise required for the technique render it far less popular than surface electrodes. The coordination of the EMG and detrusor activity is most helpful during the voiding phase, when failure to relax the pelvic floor can be indicative of pathology. Similarly, recruitment of activity should be noted with BCR and increased abdominal pressure, such as occurs during coughing. VURDS can be useful in the demonstration of anatomy in the upright position, and because the bladder and outlet are visualized in real time, it can confirm incontinence in patients in whom the diagnosis is difficult and can provide an accurate measure of leak point pressure. It is also helpful to assess the bladder outlet in patients in whom dysfunctional voiding, primary bladder neck obstruction, or detrusor-sphincter dyssynergia are suspected. Patients can also be evaluated for vesicoureteral reflux (VUR) and bladder or urethral diverticula. Assessment of detrusor pressures in the face of reflux or a large bladder diverticulum can provide important information that would be missed without video-imaging.

Recent attention has been placed on scientifically establishing the role and clinical value of UDS. The VALUE study, a multi-institutional, randomized controlled trial published in 2012, demonstrated that UDS before mid-urethral sling placement for uncomplicated SUI did not change management (Nager et al., 2012). For the index patient with uncomplicated SUI and when incontinence is demonstrated on examination, physicians may omit urodynamic testing (Kobashi et al., 2017). However, it is important to note that the worth of a test is not solely in its diagnostic accuracy, but also in the improvement of the outcomes of subsequent interventions. UDS is frequently used in the evaluation of patients with PFDs and can be helpful in counseling. Suboptimal outcomes of anti-incontinence procedures are generally attributed to intrinsic sphincter deficiency (ISD), DO, or baseline dysfunctional voiding. The deliberation regarding the merit of these theories and the ability of UDS to accurately establish these conditions continues. In a study of 655 women with positive stress tests, 10% did not demonstrate urodynamic-SUI (UDS-SUI) (Nager et al., 2007). A meta-analysis based on a Medline search of the literature between 1975 and 1998 suggested that UDS has a positive predictive value (PPV) of only 56% and 79% for pure SUI and SUI with other abnormalities, respectively, and a positive cough test has a PPV for the same of 55% and 91%, respectively (Harvey and Versi, 2001). The Urinary Incontinence Treatment Network (UITN) reported that UDS did not predict postoperative voiding dysfunction or the risk of the need for postoperative surgical intervention (Lemack et al., 2008). In another retrospective study in women who underwent retropubic mid-urethral sling placement for treatment of mixed incontinence, the median opening detrusor pressure was higher in women with postoperative DO than in those with normal postoperative UDS (Panayi et al., 2009).

Much of the literature to date has been limited by the retrospective design and small cohorts of the available studies. The UITN found that the success of anti-incontinence surgery in patients who demonstrated UDS-SUI was nearly twice that of those with non–UDS-SUI, although this trend did not reach statistical significance (Nager et al., 2008). The same group showed that treatment outcomes at 1 year for women with uncomplicated demonstrable stress incontinence were not inferior in patients who did not undergo preoperative urodynamics as compared with those who did (Nager et al., 2009, 2012). Although a study by Anger et al. (2007) did not definitively establish an effect of preoperative UDS specifically on sling outcomes, there was a clear demonstration of a twofold (significant) increased likelihood of undergoing postoperative UDS studies in those patients who did not undergo the study preoperatively as compared with those who did.

With the implementation of health care reform in 2014, cost-effectiveness is at the forefront of discussion. Based on decision-analytic (hypothetical) models, one group deemed UDS not cost-effective relative to the basic office evaluation (Weber and Walters, 2000; Weber et al., 2002). However, one must remain mindful that UDS provides information, not only about the overall diagnosis, but also regarding important subtle findings that may direct the clinician in treatment planning and counseling (Patel and Chapple, 2008; Summitt et al., 1992). Although it has been suggested that UDS may not be necessary or useful in straightforward non-neurologic patients who would be considered for initial conservative management (Colli et al., 2003; National Institute for Health and Clinical Excellence, 2006, Winters et al., 2012), others have shown that as many as 20% of patients with presumed pure SUI may have UDS findings that might alter their treatment or outcomes (Digesu et al., 2009).

Reproducibility of UDS studies as well as the interpretation of the examination has been questioned by several studies (Gacci et al., 2007; Gupta et al., 2004; Van de Beek et al., 1997; Zimmern et al., 2006). Others have demonstrated that intraobserver interpretation (interpretation repeated by the same individual) is superior to interobserver interpretation (same study read by two different individuals) for both pressure-flow analyses (Digesu et al., 2003) and filling/voiding studies (Whiteside et al., 2006). Still others have demonstrated no difference in interobserver and intraobserver interpretation, but that live interpretation of a study provides different readings than post-hoc interpretation, suggesting that intangible experiential factors may play a role in the interpretation of UDS studies (Smith et al., 2009).

Approximately 40% of patients with POP describe SUI symptoms (Grody, 1998)**, and UDS-SUI is demonstrated in 70% to 75% of prolapse patients** (Roovers and Oelke, 2007)**. Occult SUI unmasked by reduction of prolapse is reported to be present in 36% to 80%** (Bergman et al., 1988; Chaikin et al., 2000; Richardson et al., 1983)**, and 11% to 50% of clinically continent patients will develop de novo SUI after repair of high-grade prolapse** (Bergman et al., 1988; Borstad and Rud, 1989; Gallantine and Cespedes, 2001). Women who demonstrated preoperative UDS-SUI before sacrocolpopexy were more likely to develop postoperative SUI irrespective of whether they received a concomitant Burch colposuspension (Visco et al., 2008). Conversely, following a retrospective review of the records of 76 patients who underwent POP repair, Roovers et al. (2007) reported that no UDS parameters predicted postoperative incontinence. In an effort to determine the need for prophylactic sling placement in patients undergoing surgery for high-grade POP, Ballert et al. (2009) followed a UDS protocol designed to address the urethra in a standardized fashion. They concluded that in patients who did not subjectively describe or urodynamically demonstrate SUI preoperatively, the risk for intervention resulting from BOO after sling placement was equivalent to the risk for intervention for SUI in patients who did not receive a sling. **The Colpopexy and Urinary Reduction Efforts (CARE) trial was designed to evaluate whether a Burch colpopsusension performed at the time of sacrocolpopexy for prolapse in *stress-continent* women reduced postoperative SUI. The large prospective randomized study was stopped after the first interim analysis at 3 months when 23.8% of the women in the Burch group and 44.1% of the control group met criteria for SUI ($p < 0.001$)** (Brubaker et al., 2006). The cohort was continued at 2 years and 7 years postoperatively, demonstrating a continued advantage of prophylactic Burch for SUI at both time points, though the failure rates of sacrocolpopexy increased in both groups by the 7-year follow up (Brubaker et al., 2008; Nygaard et al., 2013).

In select patients, particularly those with OAB symptoms and/or known neurogenic bladder, UDS can be helpful in determining the risk for progression to upper tract deterioration. DO, poor compliance, detrusor-external sphincter dyssynergia (DESD), high detrusor storage pressures, VUR, and BOO all represent potential risk factors or the development of upper tract disease, particularly in those patients with sustained Pdet greater than 40 cm H_2O (Blaivas and Barbalias, 1984; Ghoniem et al., 1989, 1990; McGuire et al., 1981).

Although multichannel UDS remains the most accurate tool with which to evaluate LUT function, it is clear that multi-institutional randomized prospective studies are of dire importance in addressing many of the unanswered questions regarding the role and contribution of UDS to patient care, counseling, and optimization of treatment modalities. Further evaluation of the accuracy of the study and most importantly, the impact of UDS on patients, treatments, and treatment outcomes must be pursued. The UDS guidelines provide parameters around the use of UDS based on an exhaustive review of the current literature.

Key Points

- UDS is the most accurate tool available for the assessment of LUT function and provides information regarding urine storage and emptying as they are affected by the bladder and the bladder outlet.
- Although the use of routine UDS for straightforward incontinence is a topic of discussion, UDS should be strongly considered before intervention in patients who have a complex clinical picture resulting from failed previous treatment or surgery, mixed incontinence, obstructive symptoms, significantly elevated PVR, neurologic disease, or other medical conditions that may contribute to LUT function, such as diabetes mellitus, pelvic prolapse, or history of radiation therapy.
- “Eyeball UDS” may provide an approximate picture of the bladder capacity, sensation, stability, compliance, and outlet resistance when formal UDS is not available.
- Multichannel UDS offers extensive evaluation of LUT function. It involves direct measurement of bladder and intraabdominal pressure (Pves and Pabd, respectively) and a calculated assessment of detrusor pressure that is independent of abdominal pressure (Pdet). Therefore,

$$Pves - Pabd = Pdet$$

- Fluoroscopic imaging provides useful adjunctive information, such as the position and status of the bladder base and bladder neck, the presence of vesicoureteral reflux, and direct visualization of urinary leakage under real-time circumstances. Video imaging should be considered when the diagnosis cannot be made with certainty without simultaneous understanding of the anatomy in conjunction with the functional findings.

Radiographic Imaging

Voiding Cystourethrogram

Standard imaging studies are not necessary in the initial evaluation of women with uncomplicated incontinence (Artibani and Cerruto, 2005; Artibani et al., 2002)**. However, upper and lower urinary tract imaging in patients in whom renal damage or pelvic pathology are suspected should be performed.** Voiding cystourethrogram (VCUG) is optional in patients with recurrent UTIs, but can be helpful in the diagnosis of a urethral diverticulum or VUR. VCUG can provide valuable information regarding the contour of the bladder, the presence of VUR, the position of the bladder base with and without straining with the patient in an upright posture, and the position and configuration of the bladder neck during voiding. Fluoroscopic imaging can also provide visualization of subtle leakage with coughing or Valsalva maneuver that may be difficult to detect with direct examination.

Ultrasonography

Upper tract imaging is recommended in patients with chronic urinary retention, suspected extraurethral incontinence, untreated severe POP, and neurogenic detrusor dysfunction considered to be at high risk for renal damage. Patients with high-grade POP can develop upper tract obstruction and hydroureteronephrosis related to ureteral “kinking” caused by the prolapse. **Ultrasonography** provides a noninvasive sensitive and specific method of assessing the upper tracts for hydronephrosis. Ultrasonic imaging of the bladder neck for urinary leakage and descent during stress has also been used to diagnose SUI with documented pooled sensitivity and specificity rates in the range of 0.84 to 0.89 and 0.82 to 0.89, respectively (Martin et al., 2006b).

Translabial ultrasonography has also been shown to be beneficial in the evaluation of patients who had previously placed mesh for pelvic floor reconstruction (Staack et al., 2014). In patients who have mesh-related complications such erosion or pain and for whom the physician is planning to do revision surgery, consideration should be given to translabial ultrasonography. It may help identify the location of mesh material in the pelvis, the proximity to the urethra, and any abnormality such as twisting of the mesh material. Further, in patients who have undergone previous revision surgery, this information and continuity of the mesh material may be important preoperative information.

Magnetic Resonance Imaging

Magnetic resonance imaging (MRI) has been proposed as an ideal method by which to evaluate the anatomy of the bladder neck and urethra with good correlation with functional studies (Macura, 2006; Macura and Genadry, 2008; Macura et al., 2008). MRI has also been advocated for evaluation of pelvic floor relaxation and POP (Boyadzhyan et al., 2008), particularly in patients undergoing evaluation for complex multicompartmental pelvic floor reconstruction (Boyadzhyan et al., 2008; Macura, 2006), and has been shown to identify changes related to the uterosacral ligaments before and after surgical repair of prolapse (Martin et al., 2006a). MRI may also be helpful in identifying those patients in whom a urethral diverticulum may be present. Although urethral diverticula can cause symptoms of urinary leakage, pelvic pain, obstructive voiding symptoms, recurrent UTIs, dyspareunia, and a multitude of nonspecific symptoms, up to 20% of diverticula may be completely asymptomatic (Rovner, 2007). In patients with complaints of SUI who are found to have a urethral diverticulum, a simultaneous anti-incontinence surgery may be considered, in which case proper radiographic imaging, such as that which can be obtained with MRI, can provide anatomic information germane to optimal surgical planning.

High-resolution MRI allows detailed visualization of the urethra, the external sphincter, and the supporting structures. MRI evaluation focusing specifically on the muscle volume of the sphincter, defects in the sphincteric musculature, funneling of the bladder neck, symmetry of the pubococcygeus muscle or urethral supporting ligaments, increase in the size of the retropubic space or urethrovesical angle, and abnormal vaginal shape may be helpful in the diagnosis of SUI caused by ISD or urethral hypermobility (Macura, 2006). To facilitate assessment of POP using MRI, the HMO (H-line, M-line, organ prolapse) system was developed (Pannu et al., 2000).

Evaluation is performed using rapid half-Fourier T2-weighted images in the midsagittal plane during maximal patient straining. There are three fixed points in the HMO system: ***A***, the inferior margin of the pubic symphysis, ***B***, the posterior levator plate, and ***C***, the junction between the first and second coccygeal segments. Two fixed reference points include point *B* and the pubococcygeal line ***(PCL),*** drawn between points *A* and *C*. ***Line H,*** drawn between *A* and *B*, represents the anterior-posterior hiatal dimension. ***Line M,*** which is the shortest distance between point *B* and the PCL, represents the degree of pelvic descent. The ***O component*** comprises the shortest distance between the H line and the most caudal aspect of the evaluated organ during the Valsalva maneuver. Prolapse is graded based on the organ location relative to the H-line in centimeters.

Dynamic MRI can provide integral information in the preoperative assessment of POP, particularly in patients in whom the pelvic examination is difficult and inconclusive. The sensitivity, specificity, and positive predictive value (PPV) of MRI for has been reported to be 70% to 100%, 83% to 100%, and 97% to 100%, respectively, for cystoceles; 42% to 100%, 54% to 81%, and 33% to 60%, respectively, for vaginal vault prolapse; 87% to 100%, 80% to 83%, and 75% to 91%, respectively, for enteroceles; 83%, 100%, and 100%, respectively, for uterine prolapse, and 87%, 72%, and 66%, respectively, for rectoceles (Deval et al., 2003; Gousse et al. 2000). Other authors have found that dynamic MRI does not correlate well with clinical findings in patients with middle compartment (i.e., apical) prolapse, and much of the literature suggests that the study should be used only as an adjunct to clarify anatomy in complex cases (Cortes et al., 2004) or under investigational circumstances (Tubaro, 2005). Similarly, many authors agree that the posterior compartment is not as easily visualized on dynamic MRI. A study using intrarectal air during MRI did not demonstrate any value of dynamic MRI for evaluation for rectoceles over videoproctography, the latter of which was more sensitive in identifying rectoceles (Matsuoka et al., 2001). For optimal visualization of rectoceles, intrarectal gel is used to provide hyperintensity on T2-weighted images (Boyadzhyan et al., 2008; Law and Fielding, 2008; Macura, 2006).

Management

Incontinence Treatment Overview

The approach to treatment of incontinence is contingent on a clear understanding of the etiology and pathophysiology underlying the patient's symptoms. The clinician must first determine whether the cause of the symptomatology complex is a bladder or an outlet problem, or, not uncommonly, a combination of both. Therapeutic options should be considered with the goal of providing an individualized patient-directed treatment plan based on patient goals and risk-benefit and cost-benefit ratios. Proper representative counseling is paramount to properly align patient expectations and goals and what is possible to achieve. Adjunctive studies such as UDS may be performed (and in select situations *should* be performed) to provide complete information on which clinical decisions can be made as outlines in the SUI, OAB, and UDS guidelines (Gormley et al., 2012; Kobashi et al., 2017; Winters et al., 2012).

Management of incontinence can be categorized into nonsurgical and surgical options. Underlying causes such as UTI, BOO, bladder stones, foreign body, or bladder tumor should be identified and addressed first.

Treatment of incontinence must be tailored to the patient's needs, goals, and expectations and requires proper counseling on the part of the clinician. Some patients may be satisfied with protective garments and/or urine-collection devices, such as indwelling or condom catheters, or barriers, such as urethral plugs or external occlusion devices. Intervention for patients with urgency incontinence may range from behavioral and dietary modification to biofeedback or pharmacotherapy. Per the OAB guidelines, behavioral therapy (e.g. fluid management, dietary modification, and bladder training) is considered to be the first line of therapy (Gormley et al., 2012). Medications can be added subsequently, but are technically considered to be second-line therapy. Sacral neuromodulation, onabotulinum toxin A detrusor injection, and enteric augmentation of the bladder may be considered in patients with refractory symptoms.

Similarly, patients with SUI may benefit variably from conservative measures using pelvic floor muscle exercises, biofeedback, electrical stimulation, and pharmacotherapy. Urethral bulking injection therapy can provide an intermediate option between nonsurgical and surgical therapies, but surgery remains the mainstay of treatment for SUI. Although needle suspensions remain only as a point of historic discussion, retropubic suspensions have persisted as a reasonable treatment option for SUI. However, slings, using a variety of materials, insertion approaches, and anchoring techniques, have effectively become the standard options for women with SUI. In 2011, the Food and Drug Administration released a safety communication (FDA website) regarding mesh placed transvaginally specifically for the repair of pelvic prolapse (FDA, 2011a, 2011b). Unfortunately, subsequent media communication regarding mesh litigation created patient confusion and concern prompting a joint response from the Society of Urodynamics, Female Pelvic Medicine and Urogenital Reconstruction (SUFU) and the American Urogynecology Society (AUGS) in 2014 (SUFU and AUGS websites). Then, in April 2019, the FDA ordered all manufacturers of surgical mesh intended for transvaginal repair of anterior compartment prolapse (cystocele) to stop selling and distributing their products immediately. SUFU and AUGS have since updated their communications to reflect this new FDA communication.

Injection therapy has not proven a particularly viable option for the treatment of male SUI (which occurs most commonly after prostatectomy for treatment of adenocarcinoma of the prostate), and follow-up of outcomes with male slings is still early. In a review of the literature, Cerruto et al. (2013) reported on a pooled cure rate from 160 studies, none of which were controlled). At a median follow-up of 15 months, 77.4% were “cured.” The artificial urinary sphincter (AUS) remains the prevailing treatment option for postprostatectomy incontinence. The AUS has also rarely been used for treatment of SUI in women. In the fortunately rare cases of complete urethral devastation, bladder neck closure or urinary diversion can be considered.

Pelvic Prolapse Treatment Overview

New techniques have been explored to improve on the traditional pelvic floor reconstructive approaches that depend on the inherently compromised tissues of the POP patient. The use of synthetic and biological graft materials to improve the integrity and durability of POP repairs have become popularized over the past decade, although graft use remains a point of robust discussion and debate. Novel anatomic approaches and “kits” have been developed and have resulted in a dramatic increase in the number of clinicians participating in pelvic floor reconstruction, but controversy surrounding the safety of synthetic mesh graft has quickly changed the landscape again.

The goal of POP repair is to restore the normal anatomy and function of the vagina and the lower urinary and GI tracts. The decision regarding whether to proceed with a transvaginal or a transabdominal approach is dependent on which of the three compartments is affected, the degree of prolapse, and patient and surgeon preference. Apical prolapse involving the uterus typically results in a hysterectomy, although uterine-sparing techniques can be performed. Posthysterectomy apical prolapse can be addressed transvaginally with a uterosacral ligament suspension or a sacrospinous ligament fixation. Several contemporary devices that aim to facilitate high prolapse reduction have been introduced, but follow up is early. Nevertheless, the sacrocolpopexy, a transabdominal approach that can be performed either open or minimally-invasively using laparoscopy or robotic assistance, remains the gold standard repair for apical prolapse. A *Y*-shaped mesh typically composed of polypropylene is attached to the apex of the vagina and bridged to the sacrum to return the vagina to its normal axis.

New techniques of pelvic floor reconstruction continue to emerge parallel with increasing efforts to understand pelvic floor anatomy and function. A comprehensive overview of current surgical management of pelvic prolapse is presented in Chapter 112.

Conclusion

The ultimate goal of pelvic floor reconstruction is to restore the normal anatomy and function of the vagina, bladder, and surrounding structures. Proper evaluation of the pelvic floor anatomy and function should theoretically maximize the probability of favorable outcomes. Additionally, with a growing emphasis on QoL enrichment and a simultaneously increasing cost of health care, along with implementation of the Affordable Care Act, economically sound and durable treatments are the aspiration. Accordingly, efforts to develop methods by which to evaluate and quantify symptoms and assess outcomes continue. New techniques designed to provide safe and successful options to achieve maximal symptom relief and QoL improvement continue to evolve, and tissue engineering is an exciting new frontier. As our comprehension of the pelvic floor advances, further approaches to treat PFDs will undoubtedly arise.

Evaluation and Management of Men With Urinary Incontinence

Riyad Tasher Al-Mousa MBBS, SSCU, FEBU, MSHA, Hashim Hashim MBBS, MRCS (Eng), MD, FEBU, FRCS (Urol)

Urinary incontinence (UI) is defined by the International Continence Society as the complaint of any **involuntary loss of urine** (Abrams et al., 2002) or, in other words, any leakage of urine. It is part of storage lower urinary tract symptoms (LUTS). LUTS are classified into bladder storage, voiding, and post-micturition symptoms (Table 113.1). UI can result from a variety of causes. Potential risk factors for UI include increased age, infection, functional and cognitive impairment, neurologic disorders, diabetes, prostatectomy, and intake of drugs and alcohol. The acronym **DIAPPERS** can be used to list the most common causes of UI, especially in the elderly population, including delirium, infection, atrophic urethritis, pharmacologic agents, psychiatric illness, endocrine disorders, reduced mobility, and stool impaction (DuBeau, 2002). It is therefore important to understand the cause of the UI and to evaluate and assess appropriately the men who are suffering with UI to manage them accordingly, because this condition can be a social and hygienic problem that affects quality of life (QoL).

TABLE 113.1

Classification of Lower Urinary Tract Symptoms

STORAGE	VOIDING	POST-MICTURITION
• Urgency • Urinary incontinence • Increased daytime frequency • Nocturia	• Slow stream • Splitting/spraying • Intermittency • Hesitancy • Straining • Terminal dribbling	• Post-micturition dribbling • Feeling of incomplete emptying

UI should be **described by specifying relevant factors** such as type, frequency, severity, precipitating factors, social impact, effect on hygiene and QoL, the measures used to contain the leakage, and whether the individual seeks or desires help because of UI. The condition must be distinguished from sweating or urethral discharge.

UI in men is prevalent but less so than in women. It has not been well investigated and reported compared with the data available about UI in women, but Ancient Egyptian manuscripts detailed the existence of male incontinence 4000 years ago. UI in men is in a ratio of about 1 : 2 compared with UI in women. Prevalence in men varies from 1% to 39% depending on the definition used, variation in populations, response options, survey methods, and participation rates (Tikkinen et al., 2013). In a population survey in Canada, 5.4% of male respondents presented with UI (26% had stress urinary incontinence [SUI], 15% had mixed urinary incontinence [MUI], and 58% had urgency urinary incontinence [UUI]) (Bettez et al., 2012). In the EpiLUTS study (Coyne et al., 2012), the prevalence of UI in men was 46%. However, this included various forms of urinary symptoms, such as post-micturition incontinence, nocturnal enuresis, and urinary leakage with no definable cause. A total of 5.6% of men reported UUI only, 0.8% SUI only, 1.4% MUI, 6.3% UUI and another form of UI, and 1.2% SUI and another form of UI.

Prevalence has been shown to increase with age (Thom, 1998). Although UI was reported to be as low as 3% to 5% in young and middle-aged populations, it is estimated to range between 11% to 34% in old-aged population. However, some studies showed the racial and ethnic impact on UI in men (Wang et al., 2015). The National Health and Nutrition Examination Survey did not find any impact of race/ethnicity on prevalence of UI in men (Markland et al., 2010).

Key Points: Main Potential Risk Factors for Urinary Incontinence in Men

- Age
- Urologic infection
- Functional and cognitive impairment
- Neurologic diseases and comorbidities such as diabetes
- Drugs

- Surgery (e.g., prostatectomy)

Types of Urinary Incontinence

There are different types of UI (Abrams et al., 2002). Knowing the differences among them facilitates management of UI.

Stress Urinary Incontinence

SUI is the complaint of involuntary loss of urine on effort or physical exertion (e.g., sporting activities), or on sneezing, laughing, or coughing and not caused by a bladder contraction (Abrams et al., 2002). In other words, SUI is effort-related or activity-related incontinence, and this appellation may be preferred in some languages to avoid confusion with psychological stress. SUI occurs when the intra-abdominal pressure exceeds the intra-urethral pressure. SUI is more common in women (Haylen et al., 2010) than in men and usually occurs in men only after a prostatectomy, in which the external urethral sphincter is damaged.

Urgency Urinary Incontinence

UUI is the complaint of involuntary loss of urine associated with urgency. It was formerly known as urge urinary incontinence (Abrams et al., 2002). However, because it must be preceded by urgency, the terminology has changed to urgency urinary incontinence (Abrams et al., 2009; Toozs-Hobson et al., 2012). It is part of the **overactive bladder (OAB) syndrome,** and 90% of men who experience UUI will have detrusor overactivity (DO) on urodynamic studies, which leads to a rise in intravesical pressure that overcomes the outlet resistance (Hashim and Abrams, 2006). Patients who suffer with UUI have *wet OAB*.

Mixed Urinary Incontinence

MUI is the complaint of involuntary loss of urine associated with urgency and also associated with effort, physical exertion, sneezing, or coughing. Thus those with MUI experience UUI and SUI (Abrams et al., 2002). This condition is uncommon in men, although it may occur after prostatectomy.

Nocturnal Enuresis

Nocturnal enuresis is the **complaint of intermittent incontinence that occurs during periods of sleep** (Hashim et al., 2017). In other words, it is wetting the bed at night while asleep and not being aware of it.

Nocturnal enuresis has an estimated prevalence of nearly 10% in children aged 7 years. However, in 2% to 3% of children, it may persist into adulthood (Vande Walle et al., 2012). Nocturnal enuresis may also manifest later in life, and it is an important symptom, especially in men, because it may indicate that these men are in high-pressure chronic urinary retention, which can be associated with upper tract dilation and the risk of renal failure. Nocturnal enuresis is different from nocturia, which is **waking to pass urine during the main sleep period** (Hashim et al., 2017).

Continuous Urinary Incontinence

Continuous urinary incontinence describes the complaint of **continuous involuntary loss of urine** without normal voiding (Toozs-Hobson et al., 2012). This is a rare symptom and only exists when there is a fistula, for example, a prostate-rectal fistula, major sphincteric abnormalities such as exstrophy of the bladder or epispadias, or in cases with ectopic ureteral orifices. Sometimes men describe severe incontinence as continuous, when the underlying cause may be related to SUI, UUI, or MUI.

Incontinence Associated With Chronic Retention

It is commonly known as **overflow incontinence,** but this is no longer a recommended term by the International Continence Society (ICS). It is due to retention of urine and failure of the bladder to empty, and it may be dangerous in neurogenic patients because of the risk of autonomic dysreflexia in patients with spinal cord injuries above T10.

Other Types of Urinary Incontinence

Other relatively rare types of UI such as postural urinary incontinence are the **complaint of involuntary loss of urine associated with change of body position**, for example, seating after walking or rising from a seated or lying position. Insensible urinary incontinence is a complaint of UI when the patient is unaware of how it occurs but becomes aware that he is wet (Toozs-Hobson et al.,

2012).

Post-micturition leakage or dribble evokes complaints of **involuntary leakage of urine after the completion of micturition and occurring after the man has dressed himself, usually after he has left the toilet** (Abrams et al., 2002).

Functional incontinence is another type of UI. It is **the inability to reach the toilet properly because of cognitive, functional, or mobility problems in the absence of impaired lower urinary tract system.** This type of UI can happen in elderly or disabled patients. Also, UI may be situational; for example, the report of incontinence during sexual intercourse in women is termed coital incontinence. Giggle incontinence occurs when girls are giggling. Both of these types are rare in male patients.

Key Points: Types of Urinary Incontinence in Men

- SUI
- UUI
- MUI
- Nocturnal enuresis
- Continuous UI
- UI associated with chronic retention
- Others

Evaluation

History

Men with symptoms of UI must be evaluated with a **thorough history and directed physical examination.** It is important to enquire about the following:

- When do they leak? For example, when they cough, when they have urgency, at night while asleep, or at other times
- How often do they leak? For example, every night, daily, or another frequency
- Are there any precipitating factors that make leakage worse? For example, cold weather, putting the key in the door (latch-key incontinence), or other factors
- Was there any previous surgery to the prostate or bladder or was there major abdominal surgery that could have led to damage to the sacral plexus?
- How much do they leak? For example, wet the underwear, flood the outer clothing or floor, or other amounts
- Does the patient wear pads? If so, what type of pads, how many pads, what size of pads, or what other containment products are used, such as condom catheter or perhaps a change of underwear in the event of a leak?
- Has the patient tried any medications, and, if so, what medications does he take?
- Are there any neurologic problems and/or back pain that may suggest a neurologic cause for UI?
- How is the patient's sexual, erectile, and bowel function?
- What are his most bothersome symptoms?

A general medical, surgical, and social history must be obtained, including drug allergies, smoking habits, and quantifying any alcohol or caffeine intake.

Physical Examination

An examination, with the patient in a lying position, should include the following:

- The abdomen to check for surgical scars and to feel for any masses and especially for a distended bladder and hernias
- The external genitalia to examine the foreskin and external urethral meatus because some men may be suffering with *UI with chronic retention* resulting from a stenosis of the external urethral meatus or a severe phimosis
- The prostate via a digital rectal examination to feel the size and consistency of the prostate, assess if there is any pain on feeling the prostate to suggest prostatitis, as well as asking the patient to perform a pelvic squeeze to assess the strength of the pelvic floor
- The perineal skin, the anal canal and lower rectum to feel for anal tone and sensation and to assess rectal emptying
- Lower-limb neurologic examination to check reflexes, spasticity, muscle strength, gait, degree of mobility, and sensation
- Mental orientation
- Cough test: After the previous examinations are completed, ask the patient to cough to see if there is any leakage, and then ask the patient to stand and to cough again to check for SUI

First-Line Investigations

After the clinical examination is completed, bedside investigations must be performed.

Measurement of Height and Weight to Calculate Body Mass Index

The **body mass index** (BMI) is a good measure of obesity, and, in men who suffer with SUI, providing advice about weight loss may be helpful. However, there is little evidence that weight loss in men is useful; the evidence is extrapolated from women suffering with SUI. Also, related to men with SUI who have an artificial urinary sphincter (AUS), the less pressure there is intra-abdominally, and therefore the less pressure transmitted to the bladder, the less likely that these men would leak through the inflated artificial sphincter. This is because the AUS is a mechanical device, usually inserted with a pressure-regulating balloon of 61 to 70 cm H_20, and if the intra-abdominal pressure exceeds that, then the patient will leak.

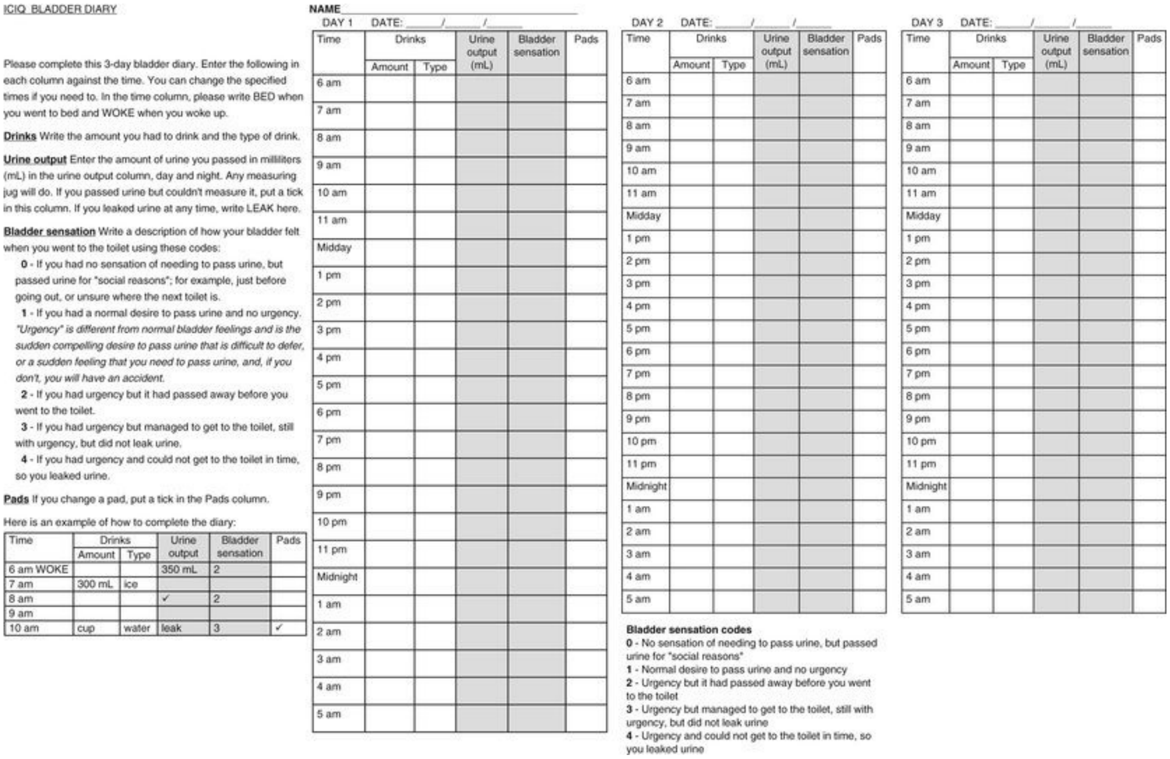
Urinalysis

Urinalysis is usually performed using a dipstick with multiple parameters, including leukocytes and nitrites (to check for infection), glucose (to check for diabetes), blood (to check for hematuria), specific gravity (to ensure adequate fluid intake), pH (to see if the urine is basic or acidic), and ketones. Although false-positive and false-negative results may be encountered, the dipstick urine test is considered to be an inexpensive vital preliminary test (Roehrborn et al., 2001).

If there is any abnormality on the dipstick urinalysis, then the specimen is sent for microscopy, culture, and sensitivity. Appropriate investigations are also then initiated, such as urine cytology, a flexible cystoscopy, and ultrasound scan of the renal tract if there is hematuria.

Bladder Diary

The **bladder diary** (Fig. 113.1) is a vital investigational tool because it provides objective information on the number of episodes the patient is leaking and the number of pads being used, voiding pattern, and how many times the patient is passing urine during the day and night, the average and maximum voided volumes and therefore bladder capacity, the type and amount of fluid being consumed, assessment for nocturnal polyuria, and whether there is any urgency.



ICIQ BLADDER DIARY

Please complete this 3-day bladder diary. Enter the following in each column against the time. You can change the specified times if you need to. In the time column, please write BED when you went to bed and WOKE when you woke up.

Drinks Write the amount you had to drink and the type of drink.

Urine output Enter the amount of urine you passed in milliliters (mL) in the urine output column, day and night. Any measuring jug will do. If you passed urine but couldn't measure it, put a tick in this column. If you leaked urine at any time, write LEAK here.

Bladder sensation Write a description of how your bladder felt when you went to the toilet using these codes:

0 - If you had no sensation of needing to pass urine, but passed urine for "social reasons"; for example, just before going out, or unsure where the next toilet is.

1 - If you had a normal desire to pass urine and no urgency. *"Urgency" is different from normal bladder feelings and is the sudden compelling desire to pass urine that is difficult to defer, or a sudden feeling that you need to pass urine, and, if you don't, you will have an accident.*

2 - If you had urgency but it had passed away before you went to the toilet.

3 - If you had urgency but managed to get to the toilet, still with urgency, but did not leak urine.

4 - If you had urgency and could not get to the toilet in time, so you leaked urine.

Pads If you change a pad, put a tick in the Pads column.

Here is an example of how to complete the diary:

Time	Drinks		Urine output	Bladder sensation	Pads
	Amount	Type			
6 am WOKE			350 mL	2	
7 am	300 mL	ice			
8 am			✓	2	
9 am					
10 am	cup	water	leak	3	✓

Bladder sensation codes

0 - No sensation of needing to pass urine, but passed urine for "social reasons"

1 - Normal desire to pass urine and no urgency

2 - Urgency but it had passed away before you went to the toilet

3 - Urgency but managed to get to the toilet, still with urgency, but did not leak urine

4 - Urgency and could not get to the toilet in time, so you leaked urine

FIG. 113.1 International Consultation on Incontinence Questionnaire Bladder Diary (ICIQ-BD).

Several different bladder diaries are available. However, none of these diaries has been fully validated except for the International Consultation on Incontinence Questionnaire Bladder Diary **(ICIQ-BD)** (Bright et al., 2014).

The number of days a bladder diary must be completed has also been the subject of several publications, and the most recent recommendation is that a 3-day bladder diary would offer the same information as a 7-day one without being too exhaustive for patients (Dmochowski et al., 2005). It is important, however, to tell patients to try to complete the diary so that they include a combination of weekdays and weekends, and the entries should be representative of patients' day-to-day lifestyles. The ICIQ-BD validation has shown that 3 days is the appropriate length to include the day-to-day changes in frequency and so forth.

Quality-of-Life Questionnaires and Patient-Reported Outcome Measures

Patients are unlikely to suffer significant morbidity from most types of UI, but UI does cause significant impact on **QoL.** It is therefore prudent to assess the impact of UI on a patient's QoL with a validated questionnaire.

The International Prostate Symptom Score (IPSS or American Urological

Association-SI [AUA-SI]) is the most commonly used questionnaire for men. However, this questionnaire is useless for men with UI, simply because the IPSS does not measure incontinence.

The ICIQ-UI short form (**ICIQ-UI-SF**; Fig. 113.2) is a simple, short questionnaire that helps differentiate between SUI and UUI (Avery et al., 2004). The alternative is the longer form, ICIQ-male LUTS questionnaire (ICIQ-MLUTS; eFig. 113.3), which includes the advantages of asking about the storage and voiding symptoms covered by the IPPS and asking about the bother of each (Abrams et al., 2006).

Today's date

Many people leak urine some of the time. We are trying to find out how many people leak urine, and how much this bothers them. We would be grateful if you could answer the following questions, thinking about how you have been, on average, over the PAST FOUR WEEKS.

1 Please write in your date of birth: ☐☐ ☐☐ ☐☐

DAY MONTH YEAR

2 Are you *(tick one)*: Female ☐ Male ☐

3 How often do you leak urine? *(Tick one box)*

never	☐	0
about once a week or less often	☐	1
two or three times a week	☐	2
about once a day	☐	3
several times a day	☐	4
all the time	☐	5

4 We would like to know how much urine you think leaks.
How much urine do you usually leak (whether you wear protection or not)?
(Tick one box)

none	☐	0
a small amount	☐	2
a moderate amount	☐	4
a large amount	☐	6

5 Overall, how much does leaking urine interfere with your everyday life?
Please ring a number between 0 (not at all) and 10 (a great deal)

0 1 2 3 4 5 6 7 8 9 **10**

not at all a great deal

ICIQ score: sum scores 3+4+5 ☐ ☐

6 When does urine leak? *(Please tick all that apply to you)*

- never – urine does not leak ☐
- leaks before you can get to the toilet ☐
- leaks when you cough or sneeze ☐
- leaks when you are asleep ☐
- leaks when you are physically active/exercising ☐
- leaks when you have finished urinating and are dressed ☐
- leaks for no obvious reason ☐
- leaks all the time ☐

Thank you very much for answering these questions.

Thank you very much for answering these questions.

Copyright © "ICIQ Group" : the ICIQ-MLUTS Long Form is based on the ICS*male*

EFIG. 113.3 International Consultation on Incontinence Questionnaire

Male Lower Urinary Tract Symptoms (ICIQ-MLUTS).

The bladder diary and QoL questionnaire help not only in the assessment of patients but also in looking at treatment effects if repeated after the patient has been treated.

Pad Testing

Pad testing is a diagnostic tool to detect and measure urine loss by weighing an absorbent pad before and after the test during specific period and standardized conditions. There is much controversy about the use of **pad testing** and the duration of time for which it should be performed. Should it be done for 1 hour or 24 hours? How many days should it be performed? Do pretreatment pad loss volumes predict outcomes? All these are questions that have not yet been answered by high-quality research. Also, pad testing does not help to differentiate between the different types of incontinence, especially UUI and SUI.

Most guidelines have not recommended the use of pad testing. However, pad testing can be useful in attempting to quantify the amount of leakage a patient experiences and perhaps in planning treatment accordingly. There is also disagreement in the literature as to what the definition of mild, moderate, and severe incontinence is, and whether the number of pads should be used to classify UI severity, or whether urine loss measured by pad weights should be used. Some would suggest that the use of one pad is considered mild, two to four pads is moderate, and more than four pads is severe, but patients sometimes change pads because of hygienic reasons rather than for necessity (Tsui et al., 2013). **Increased pad weight is therefore probably a better measure of the severity of UI, and usually less than 200 g/day is considered mild, 200 to 400 g/day is moderate, and more than 400 g/day is severe** (Kumar et al., 2009). However, it should be emphasized that these cut points have not been properly validated.

Urine Flow Rate and Postvoid Residual

Urine flow rates help in showing the pattern of the flow and the speed at which the patient is voiding, and ultrasound after voiding measures the postvoid residual (PVR). These measurements are inexpensive and easy to perform, and they are noninvasive. It is important, however, to learn how to interpret the measurements. A fast-rising flow rate may indicate an OAB resulting from urgency, and a slow-rising one with a long tail on the flow curve may indicate bladder outlet obstruction. If there is a high PVR, the obstruction may cause chronic retention, and if this is associated with high bladder-filling pressures, then night-time UI during sleep may occur.

It is recommended that at least two flows be performed to ensure that they are representative of the manner in which the patient normally voids (Garcia-Mora et al., 2013; Reynard et al., 1996). However, the latest ICS Good Urodynamic Practice document does suggest that one flow is sufficient if it is representative of the patient's normal voiding pattern (Rosier et al., 2017).

Measurement of Prostate-Specific Antigen

There is much controversy about prostate-specific antigen (PSA) testing, which will not be discussed here. However, if the testing is not going to change management, and if the digital rectal examination was normal, it should not be performed unless the patient requests it and is fully counseled about PSA testing.

Blood Tests

Blood tests should be tailored according to the patient history and examination. If the postvoid residual is high or a patient is diabetic, then renal function tests and glucose are indicated (Hill et al., 2013). In general, if it is an index case of UUI or SUI with no PVR, then blood tests are not indicated; however, the clinician may opt to perform blood tests because they are helpful in assessing renal function, and it would be difficult to select those patients with renal insufficiency (Madersbacher et al., 2004).

Advanced Investigations

Imaging.

Imaging with a plain x-ray radiograph or urinary tract ultrasound are not indicated in patients with UI, unless there is concern that the patient may be suffering with upper tract abnormalities, high postvoid residual (PVR), or if there is suspicion of stones (Abrams et al., 2008).

Endoscopy.

Urethrocystoscopy is indicated in patients suspected of having a urethral stricture, bladder outlet obstruction, or another pathology seen on

urinalysis, such as blood, or flow tests such as a high PVR (Sammer et al., 2015).

Urodynamic Studies.

Urodynamic studies (UDS), or urodynamics, include studies of the physics and physiology of the lower urinary tract (LUT). It is the gold standard to assess LUT function and dysfunction. Technically this includes flow rates. In everyday practice, however, the term *UDS* means invasive urodynamic testing and includes filling cystometry and voiding pressure/flow studies. It includes quality control, data analysis, and systemic documentation.

The general underlying principle when performing urodynamics is that it should not be performed unless it is going to change the management of the patient and unless it would provide the clinician with more information that would alter his or her management of the patient. Therefore, following baseline investigations, most major international guidelines including the International Consultation on Incontinence, the European Association of Urology, and the American Urological Association recommend that patients be treated with conservative therapy and medical therapy before performing urodynamics, and if these treatments fail to control the patient's symptoms and the patient would like to have, or needs, a surgical intervention, then that is when urodynamics is performed—that is, **before invasive therapy** (Winters et al., 2012).

Urodynamics should be considered in the following situations:

- To identify factors contributing to LUT dysfunction and to assess their relevance
- To predict the consequences of LUT dysfunction on the upper tracts
- To predict the consequences and outcomes of therapeutic intervention
- To confirm and/or understand the effects of interventional techniques
- To investigate the reasons for treatment failure
- Before undergoing any surgical intervention

Filling cystometry aims to define how the bladder and urethra behave during the storage phase. In other words, in an index non-neurologic patient, **the bladder can either be normal, or there is detrusor overactivity (DO), or there is poor compliance.** If the patient leaks during filling cystometry when a DO wave exists, that then is termed ***detrusor overactivity incontinence*** **(DOI)**. **It is important to mark on the urodynamics trace whether urgency was experienced at that time and whether there were any provocative maneuvers.**

The urethra, that is, the external urethral sphincter, can either be competent or incompetent during filling cystometry. If it is competent, then the patient will be continent and will not experience SUI. The patient is usually asked to perform Valsalva maneuvers or repeated coughs in the upright position when 200 mL of fluid have been instilled into the bladder. If the patient leaks, then the urethra is incompetent and the pressure at which leakage starts, the abdominal (Valsalva or cough) leak-point pressure, is recorded. Valsalva and coughs are also repeated at the end of the test at maximum capacity if the patient did not leak at 200 mL of bladder filling. **If the patient leaks on increasing intra-abdominal pressure, then he is said to have urodynamic stress incontinence (USI) instead of SUI; SUI is a symptomatic clinical diagnosis before urodynamics is performed.**

One important scenario that can occur during urodynamics is **cough-induced DOI, which happens when the patient coughs. This action initiates an involuntary detrusor contraction (DO), and the patient leaks because of the DO contraction rather than because of the raised intra-abdominal pressure generated by the cough.** Clinically it sounds as if the patient is leaking because of SUI, whereas the urodynamics shows that he has cough-induced DOI.

If during UDS it is difficult to be certain whether the man has USI or cough-induced DOI, then it may be helpful to fill the bladder with the man in a lying position, because then DO is less likely to occur. Then the patient is asked to cough to determine whether he leaks in the absence of DO, which would confirm the diagnosis of USI. If he does not leak with coughing, that is then good evidence that he only has DOI. If he leaks while lying down without DO, then the patient also has USI and therefore has DOI and USI, that is, mixed urodynamically proven UI.

After urodynamics is performed and the diagnosis is confirmed, invasive surgical treatment can be offered.

Key Points: Initial Evaluation of Patients With

Urinary Incontinence

Essential

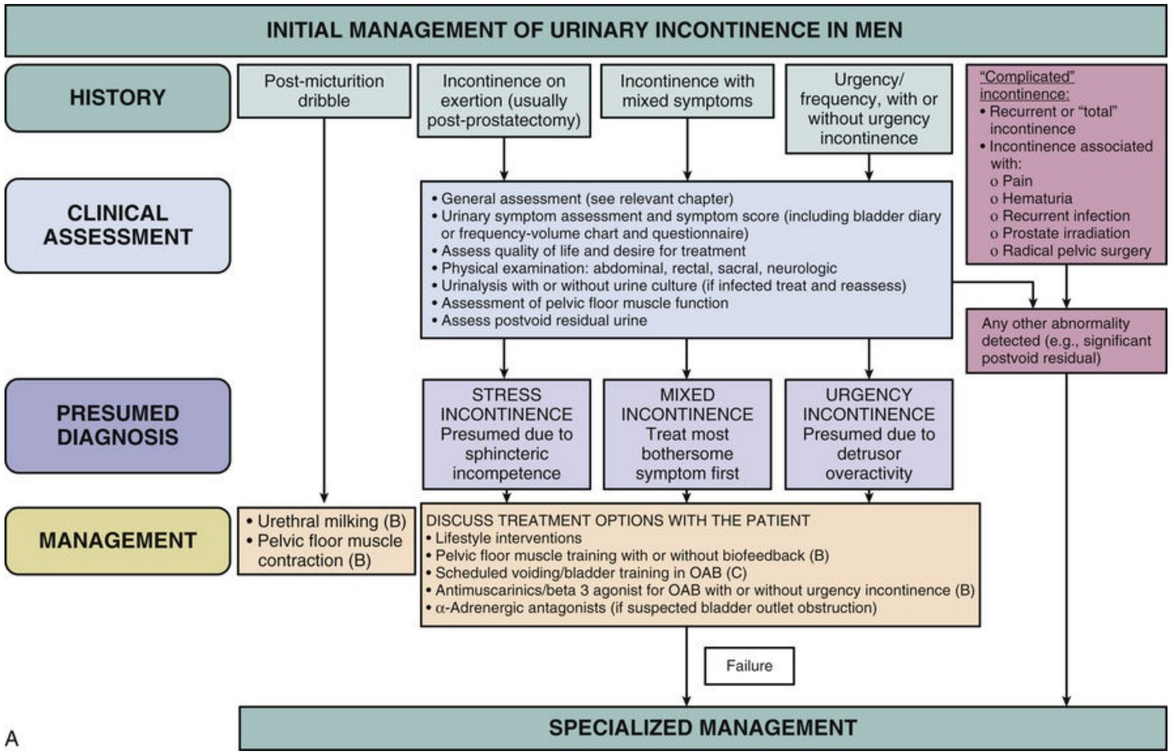
- History and examination
- Measurement of height and weight to calculate BMI
- Dipstick urinalysis
- Bladder diary, for example, ICIQ-BD
- QoL questionnaire, for example, ICIQ-UI-SF
- Urine flow rate and measurement of PVR

Optional

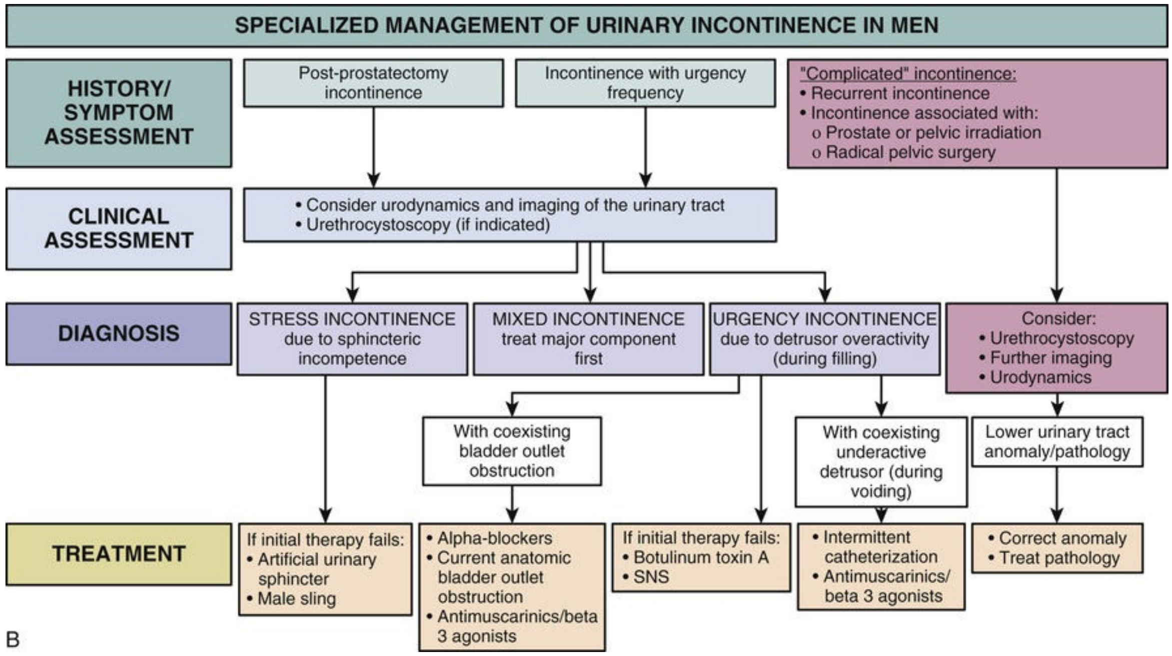
- PSA
- Blood tests, for example urea and electrolytes
- Renal tract imaging
- Endoscopy
- UDS

Principal Methods of Treating Men With Urinary Incontinence

The aim of treatment is to control continence and improve QoL. Treatment (Fig. 113.4) of patients suffering with UI can be divided into the following:



INITIAL MANAGEMENT OF URINARY INCONTINENCE IN MEN
HISTORY
Post-micturition dribble
Incontinence on exertion (usually post-prostatectomy)
Incontinence with mixed symptoms
Urgency/ frequency, with or without urgency incontinence
"Complicated" incontinence:
• Recurrent or "total" incontinence
• Incontinence associated with:
o Pain
o Hematuria
o Recurrent infection
o Prostate irradiation
o Radical pelvic surgery
CLINICAL ASSESSMENT
• General assessment (see relevant chapter)
• Urinary symptom assessment and symptom score (including bladder diary or frequency-volume chart and questionnaire)
• Assess quality of life and desire for treatment
• Physical examination: abdominal, rectal, sacral, neurologic
• Urinalysis with or without urine culture (if infected treat and reassess)
• Assessment of pelvic floor muscle function
• Assess postvoid residual urine
Any other abnormality detected (e.g., significant postvoid residual)
PRESUMED DIAGNOSIS
STRESS INCONTINENCE Presumed due to sphincteric incompetence
MIXED INCONTINENCE Treat most bothersome symptom first
URGENCY INCONTINENCE Presumed due to detrusor overactivity
MANAGEMENT
• Urethral milking (B)
• Pelvic floor muscle contraction (B)
DISCUSS TREATMENT OPTIONS WITH THE PATIENT
• Lifestyle interventions
• Pelvic floor muscle training with or without biofeedback (B)
• Scheduled voiding/bladder training in OAB (C)
• Antimuscarinics/beta 3 agonist for OAB with or without urgency incontinence (B)
• α-Adrenergic antagonists (if suspected bladder outlet obstruction)
Failure
SPECIALIZED MANAGEMENT
A



SPECIALIZED MANAGEMENT OF URINARY INCONTINENCE IN MEN
HISTORY/ SYMPTOM ASSESSMENT
Post-prostatectomy incontinence
Incontinence with urgency frequency
"Complicated" incontinence:
• Recurrent incontinence
• Incontinence associated with:
o Prostate or pelvic irradiation
o Radical pelvic surgery
CLINICAL ASSESSMENT
• Consider urodynamics and imaging of the urinary tract
• Urethrocystoscopy (if indicated)
DIAGNOSIS
STRESS INCONTINENCE due to sphincteric incompetence
MIXED INCONTINENCE treat major component first
URGENCY INCONTINENCE due to detrusor overactivity (during filling)
Consider:
• Urethrocystoscopy
• Further imaging
• Urodynamics
With coexisting bladder outlet obstruction
With coexisting underactive detrusor (during voiding)
Lower urinary tract anomaly/pathology
TREATMENT
If initial therapy fails:
• Artificial urinary sphincter
• Male sling
• Alpha-blockers
• Current anatomic bladder outlet obstruction
• Antimuscarinics/beta 3 agonists
If initial therapy fails:
• Botulinum toxin A
• SNS
• Intermittent catheterization
• Antimuscarinics/ beta 3 agonists
• Correct anomaly
• Treat pathology
B

FIG. 113.4 International Consultation on Incontinence algorithm on initial (A) and specialized (B) management of urinary incontinence in men. (From Abrams P, Cardozo L, Wagg A, et al.: Sixth International Consultation on Incontinence. *Incontinence* 2565–2567, 2017.)

Conservative

- Lifestyle changes: weight loss, stopping smoking, exercise, food and fluid manipulation

Lifestyle changes have been shown to have a positive impact on UI. Healthy eating, weight loss in overweight and obese patients (For SUI), smoking cessation, and reduced alcohol consumption are primary measures that may help to improve UI and related LUTS (Davis et al., 2013)

- Pelvic floor muscle training:

Effective first-line therapy mainly in men with postprostatectomy incontinence. Studies suggested better effect when exercises commence preoperatively (Dijkstra-Eshuis et al., 2015).

- Bladder training:

Scheduled voiding regimen and double voiding if necessary is a valid method to reduce UI and improve bladder capacity. Some studies suggested that bladder training was equivalent to pharmacologic therapy (Burgio et al., 2011).

Pharmacological (See details in Chapter 120 and Management of Different UI Types in Men.)

- Antimuscarinics/anticholinergics
- β3 agonist
- Serotonin norepinephrine reuptake inhibitors
- Others: alpha-blockers and PDE5 inhibitors

Minimally invasive (See details in Chapter 122 and Management of Different Urinary Incontinence Types in Men.)

- Botulinum toxin A
- Posterior tibial nerve stimulation
- Sacral neuromodulation
- Urethral bulking agents

Major surgery

- Augmentation cystoplasty
- Continent and incontinent urinary diversion
- Male slings
- Artificial urinary sphincter

Management of Different Urinary Incontinence Types in Men

Treatment of Urgency Urinary Incontinence

Initial conservative treatment of UUI includes behavioral modifications and lifestyle changes, such as reducing fluid input by 25% as long as the patient is drinking more than 1 L/day (Hashim and Abrams, 2008), stopping smoking, reducing weight, and avoiding caffeinated and fizzy drinks that may irritate the bladder (Hashim and Al Mousa, 2009). **The patient is also taught bladder training and pelvic floor muscle training** to supplement the fluid manipulation. These treatments must be attempted for at least 6 weeks to obtain benefit, and they should ideally be tried for 3 months.

If the previously outlined treatment fails, the patient can then be offered antimuscarinic therapy, if there are no contraindications. At least two antimuscarinics were recommended to be tried for at least 4 weeks each, starting at a low dose and building up to a maximum dose. Some studies, however, support the use of a single antimuscarinic then moving to other forms of management options (Chancellor et al., 2014). **There are seven antimuscarinics on the market** in the United Kingdom (oxybutynin, tolterodine, fesoterodine, solifenacin, darifenacin, propiverine, and trospium chloride). Most are oral tablets, but oxybutynin is also available in a topical gel formulation (in the United States) and as a skin patch. Each has advantages and disadvantages, and the choice of one in favor of the other depends on several factors, including licensing in the respective country, local guidelines, and clinician and patient preferences. All of the antimuscarinics have Level 1 evidence and Grade A recommendations for their use. Trial analysis (Madhuvrata et al., 2012) showed similar efficacy with all kinds of antimuscarinic with preferred choice of extended release formula over the immediate-release formula. Solifenacin may be preferred over tolterodine for better efficacy and less risk of dry mouth. Also, fesoterodine may have better efficacy over tolterodine but higher risk of withdrawal and discontinuation because of side effects (Madhuvrata et al., 2012). Trospium chloride, which is a nonselective quaternary amine antimuscarinic drug, which crosses the blood-brain barrier to a limited extent, only compared with other antimuscarinics.

Clinically, it seems to have good efficacy with no cognitive effect (Chancellor et al., 2012). The combination of two antimuscarinics or doubling the recommended dose of some antimuscarinics could be an option in selected patients to increase efficacy (Kosilov et al., 2014a) but is an off-license use.

If patients are unable to tolerate antimuscarinics or the antimuscarinics have failed to control symptoms, then patients can be prescribed **mirabegron, which is a β_3-agonist lipophilic medication that is metabolized in liver, and more than 50% is excreted in the urine. It has been licensed for the treatment of OAB in several countries, including the United States, the United Kingdom and other European countries, and Japan.** Mirabegron showed proven efficacy and superiority to tolterodine in terms of urinary incontinence episodes and frequency (Khullar et al., 2011).

Although some studies showed no difference in terms of efficacy between antimuscarinics and the β_3-agonist, the β_3-agonist does have advantages over antimuscarinics with respect to side effects such as less dry mouth and constipation (Chapple et al., 2014; Rossanese et al., 2015). However, it can cause palpitations and headaches resulting from hypertension.

Combination therapy of an antimuscarinic with a β_3-agonist has been shown to be an effective modality of treatment. In theory, because they work on different receptors they can be used in combination. A phase II trial has shown that the combination therapy of mirabegron and solifenacin is superior to monotherapy with a safe side effect profile (Abrams et al., 2015). A phase IIIB trial has shown that the combination of mirabegron 50 mg with solifenacin 5 mg is superior to dose escalation of solifenacin from 5 mg to 10 mg with better efficacy and less side effects (Drake et al., 2016).

Other forms of combination therapies have been recognized by the AUA (American Urological Association), EAU (European Association of Urology), and NICE (National Institute for Health and Care Excellence), such as a combination of alpha-blockers and antimuscarinics or alpha-blockers and β_3 agonists as a treatment option for patient with moderate to severe LUTS (Ichihara et al., 2015; Kaplan et al., 2013; Van Kerrebroeck et al., 2013) in patients with storage and voiding symptoms. PDE-5 inhibitors have been shown to improve LUTS and UI in men (Cellek et al., 2014). They relax the smooth muscles of the prostate, bladder, and urethra and improve bladder blood flow, which ultimately improves the patient's symptoms. **Tadalafil** is the only U.S. Food an Drug Association–approved PDE-5 inhibitor for the treatment of voiding LUTS in men (Cellek et al., 2014). More often than not, conservative and medical therapies are initiated at the same time to provide patients with a quicker and better relief of symptoms.

If conservative and medical therapies fail to control symptoms and the patient requests further treatment, invasive urodynamics is then performed to confirm DO and/or DOI, and minimally invasive surgery, where indicated and available, is offered. **This can either be in the form of cystoscopic intradetrusor injections of botulinum toxin-A, percutaneous sacral neuromodulation (SNM), or percutaneous posterior tibial nerve stimulation (PTNS).**

Botox, ona-botulinum toxin A, is the only licensed formulation of botulinum toxin A, for idiopathic UUI at 100 units, and for neurogenic DO at 200 units. Patients using Botox should be warned of the risk of urinary retention (approximately 10%), and they should be able and willing to perform intermittent catheterization. In addition, the injections must be repeated on average every 6 to 9 months.

SNM involves a test phase with a wire and external stimulator for 1 to 2 weeks, and a second stage with a tined lead and battery if the first one is successful, which is usually defined as more than a 50% improvement in symptoms. Recently, the test phase has been replaced by a permanent tined lead with a longer test phase for 2 to 4 weeks that is placed percutaneously under fluoroscopy in the S3 sacral foramen alongside the sacral nerve, then if the results were satisfactory, the battery will be implanted as a second stage. The mechanism of action of SNM is not clear; however, it is believed that it modulates the nerves supplying the bladder. The battery is changed every 5 to 7 years, on average, depending on the amount of use. The cure rate of UUI is 39%, and an improvement of greater than 50% is seen in 67% of patients. Long-term success has been evaluated with more than 10 years' follow-up with sustained results (Bettez et al., 2012).

PTNS, on the other hand, although licensed for OAB in some countries, does not seem to offer the same degree of benefit as Botox or SNM, and therefore PTNS is not widely used. The response rate is 54% to 81% (Bettez et al., 2012; Peters et al., 2013). PTNS involves inserting a needle into the ankle on the tibial nerve to electrically stimulate the sacral micturition center via the S2-S4 sacral nerve plexus. It is administered as 30-minute sessions, once per week for 12 weeks, and then it is maintained after that at once per month. Patients find it laborious, especially if it means traveling for long distances to receive treatment. In theory, this treatment can be self-administered if the patients are taught how to do it. The cost is higher than antimuscarinics therapy and there are no long-term outcome data available.

If these minimally invasive treatments fail and the patient continues to be bothered by symptoms, then the only treatments remaining are major surgical operations, unless the patient prefers to use containment products such as pads or a permanent suprapubic catheter. **Surgical options include augmentation cystoplasty, in its various forms, or an ileal conduit with or without a subtotal cystectomy.** In adults, autoaugmentation is no longer recommended for the treatment of DO because of the poor long-term success of this procedure resulting from complications (Leng et al., 1999: Ter Meulen et al., 1997).

Treatment of Stress Urinary Incontinence

SUI is treated initially with pelvic floor muscle training for at least 3 months. Ideally the training should be supervised, usually with a pelvic floor physiotherapist, to allow the best chance of success (Hay-Smith et al., 2012). If this treatment fails to control symptoms, then surgical options should be considered.

The most common cause for SUI in men occurs after prostatectomy. **After radical prostatectomy, it is recommended that no surgical treatment be considered until at least 6 to 12 months subsequently, because some patients will continue to improve** (Herschorn et al., 2010). While they are waiting to improve, patients can use a penile clamp such as *Dribble-Stop*, or, more frequently, containment products are used such as a condom catheter, urethral (not recommended long term because of risk of traumatic hypospadias) or suprapubic catheter, or incontinence pads.

Duloxetine, a combination of norepinephrine and serotonin reuptake inhibitor, can also be tried (Tsakiris et al., 2008). However, this is an off-license use of the medication that has only been licensed in several countries around the world to women who are experiencing moderate to severe incontinence. The efficacy data for men are limited.

If these treatments fail to control the incontinence and patients are still bothered, then surgical treatment is often offered, usually using an artificial urinary sphincter (AUS), which is the gold standard treatment with continence rates of about 80%. Alternative to the AUS, other surgical options that have shown variable efficacy in mild to moderate cases include urethral bulking agents, fixed male slings, adjustable male slings and, occasionally, the

ProACT (Table 113.2). It is important to rule out urethral or anastomotic strictures or bladder dysfunction before undergoing surgical treatment. Injection of bulking agents to enhance coaptation of the affected sphincter showed inferior results with no proven long-term efficacy regardless of the material used (Silva et al., 2014).

TABLE 113.2

Second- and Third-Line Therapy Recommendation for Men With Stress Urinary Incontinence

RECOMMENDATIONS	GR
Consider offering duloxetine to hasten recovery of continence after prostate surgery but inform the patient about the possible adverse events.	B
Only offer bulking agents to men with mild post-prostatectomy incontinence who desire temporary relief of incontinence symptoms.	C
Do not offer bulking agents to men with severe post-prostatectomy incontinence.	C
Offer fixed slings to men with mild to moderate post-prostatectomy incontinence.	B
Warn men that severe incontinence, prior pelvic radiotherapy, or urethral stricture surgery may worsen the outcome of fixed male sling surgery.	C
Offer artificial urinary sphincter (AUS) to men with moderate to severe post-prostatectomy incontinence.	B
Implantation of AUS or artificial compression device (ACT) for men should only be offered in expert centers.	C
Warn men receiving AUS or ACT that, even in expert centers, there is a high risk of complications or mechanical failure, or a need for explantation.	C
Do not offer non-circumferential compression device (ProACT) to men who have had pelvic radiotherapy.	C

Data from Burkhard FC, Bosch J, Cruz F, et al.: EAU Guidelines on Urinary Incontinence in Adults; 2017 (website): https://uroweb.org/wp-content/uploads/EAU-Guidelines-Urinary-Incontinence-2016.pdf.

Male slings have shown good efficacy with acceptable morbidity in mild to moderate SUI (Chapple et al., 2017). Male slings are inserted either by the transobturator or retropubic approach. The AdVance male sling is a commonly used fixed male sling that consists of polypropylene mesh that is placed via the transobturator approach under the membranous urethra with cure rates ranging between 9% and 63%. The success and cure rate variations are highly related to variation in definition of success and cure (Cornel et al., 2010). Similarly, adjustable male slings were introduced to improve basic continence with the theoretical advantage of adjusting the tension postoperatively for better continence rate. Three main adjustable slings are available in the market and have been studied with some variation in terms of efficacy. The Remeex system showed a success rate of 36% to 70% with multiple readjustment and 21% mechanical failure rate (Kim, 2011). The Argus system showed a subjective success of 58% and readjustment was reported to be up to 41% (Hubner et al., 2011). The adjustable transobturator male sling (the ATOMS) system is the most recent version of adjustable male slings. It consists of an inflatable soft silicon cushion compressing the urethra that can be adjusted through a titanium port access postoperatively either in the lower abdomen or in the scrotum. Objective cure rate was reported up to 60.5% with the need of multiple system adjustments and around 27.7% explantation rate (Hoda et al., 2013; Seweryn et al., 2012). More recent long-term data suggest that the third-generation ATOMS system with a pre-attached silicon-covered scrotal port showed good efficacy, durability, and fewer adjustments in the long-term follow-up mainly with primary implantation (Friedl et al., 2016; Strini et al., 2018). However, according to international guidelines, adjustable slings showed no additional benefits over standard slings with similar morbidity (Burkhard et al., 2017).

The ProACT device consists of a compressive balloon system that is placed in the bladder neck area, and volume can be readjusted via two scrotal ports with continence success rates of up to 68% and explantation rates of up to 55% (Hubner et al., 2007; Venturino et al., 2015).

Treatment of Mixed Urinary Incontinence

Treatment of MUI is more challenging. It should be aimed at treating the most bothersome symptom first. Diagnosis of the SUI component, even on urodynamics, is sometimes difficult if UUI is the predominant type of incontinence. Initial treatment usually involves treating DO with antimuscarinics and even with Botox or SNM and then repeating the urodynamics to determine if there is a SUI component.

Treatment of Other Types of Urinary Incontinence

The other types of UI (e.g., overflow incontinence) are treated based on the underlying cause (e.g., bladder outlet obstruction) which might need Transurethral resection of the prosatate (TURP).

Enuresis

Patients with high-pressure urinary retention causing nocturnal enuresis are treated by initial catheterization to relieve the pressure in the bladder, followed by appropriate assessment with a view to using endoscopic surgery to resect, to vaporize, or to enucleate the prostate, or open removal of the prostate.

Nocturnal enuresis, without residual urine, may be related to the OAB. This can be treated with antimuscarinics and potentially with desmopressin in the melt-formulation. It can also be related to relaxation of the pelvic floor during sleeping in patients with a neobladder after cystoprostatectomy. These patients sometimes only leak at night, and treatment is usually conservative.

Post-Micturition Dribble

Treatment of post-micturition dribble has not been well studied, and there are no medications available that have been approved for this indication. The main form of treatment is pelvic floor muscle training with a strong pelvic squeeze at the end of voiding and also urethral milking (Dorey et al., 2004; Paterson et al., 1997). The man is asked to wait for a few seconds after passing urine to ensure that the bladder is empty. Then he must place the fingertips of one of his hands three-fingerbreadths behind the scrotum and apply gentle pressure in the midline and gently move the fingertips toward the base of the penis under the scrotum. The aim is to push the urine forward into the middle part of the penis. From then on, the penis is milked, squeezed, and shaken to empty any remaining urine. The process is repeated twice to ensure that no urine remains in the urethra.

Key Points: Treatment of Urinary Incontinence

Urgency Urinary Incontinence

- Fluid manipulation and lifestyle changes
- Bladder training and pelvic floor muscle training
- Antimuscarinics and/or β_3 agonists
- Botox
- SNM
- Augmentation cystoplasty

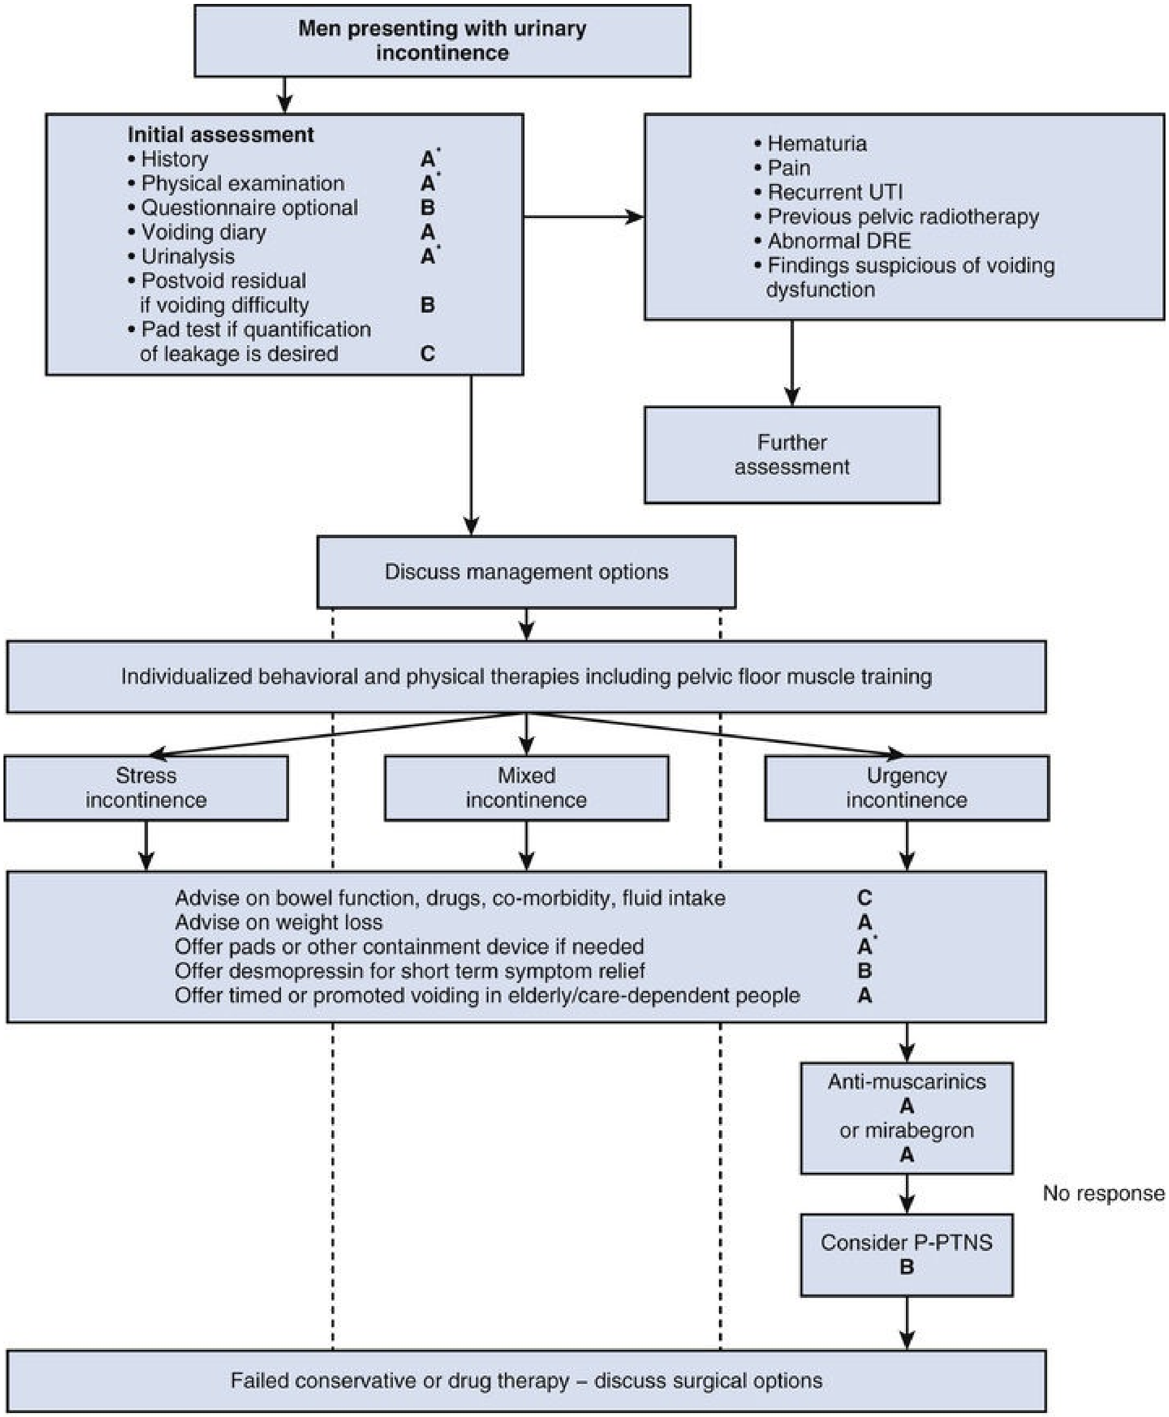
- Urinary diversion, for example, ileal conduit

Stress Urinary Incontinence

- Weight loss and lifestyle changes
- Pelvic floor muscle training
- Duloxetine (off-license)
- Penile clamp
- AUS (gold standard)
- Male sub-urethral sling (fixed or adjustable)
- ProACT balloon

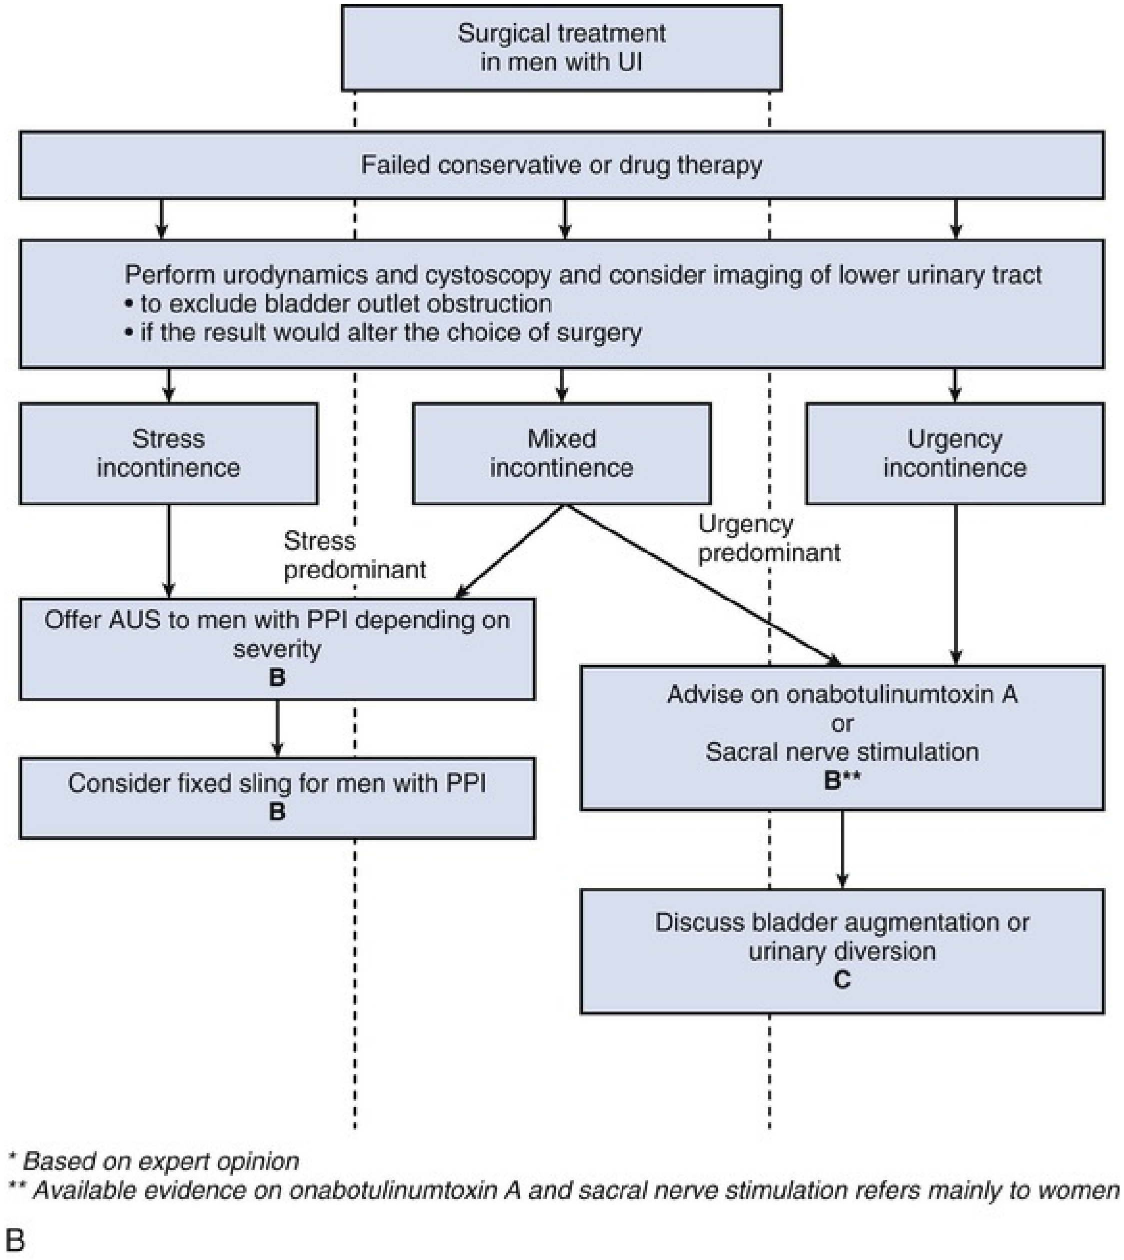
Algorithms for Management of Men With Urinary Incontinence

See Figs. 113.4 and 113.5.



Men presenting with urinary incontinence
Initial assessment
• History A*
• Physical examination A*
• Questionnaire optional B
• Voiding diary A
• Urinalysis A*
• Postvoid residual if voiding difficulty B
• Pad test if quantification of leakage is desired C
• Hematuria
• Pain
• Recurrent UTI
• Previous pelvic radiotherapy
• Abnormal DRE
• Findings suspicious of voiding dysfunction
Further assessment
Discuss management options
Individualized behavioral and physical therapies including pelvic floor muscle training
Stress incontinence
Mixed incontinence
Urgency incontinence
Advise on bowel function, drugs, co-morbidity, fluid intake C
Advise on weight loss A
Offer pads or other containment device if needed A*
Offer desmopressin for short term symptom relief B
Offer timed or promoted voiding in elderly/care-dependent people A
Anti-muscarinics A or mirabegron A
No response
Consider P-PTNS B
Failed conservative or drug therapy – discuss surgical options

A



Surgical treatment in men with UI
Failed conservative or drug therapy
Perform urodynamics and cystoscopy and consider imaging of lower urinary tract
• to exclude bladder outlet obstruction
• if the result would alter the choice of surgery
Stress incontinence
Mixed incontinence
Urgency incontinence
Stress predominant
Urgency predominant
Offer AUS to men with PPI depending on severity
B
Consider fixed sling for men with PPI
B
Advise on onabotulinumtoxin A or Sacral nerve stimulation
B**
Discuss bladder augmentation or urinary diversion
C
* Based on expert opinion
** Available evidence on onabotulinumtoxin A and sacral nerve stimulation refers mainly to women
B

FIG. 113.5 European Association of Urology conservative (A) and surgical (B) treatment algorithm of men with urinary incontinence. *AUS,* Artificial urinary sphincter; *DRE,* digital rectal examination; *PPI,* post-prostatectomy incontinence; *P-PTNS,* percutaneous posterior tibial nerve stimulation; *UTI,* urinary tract infection. (From Burkhard FC, Bosch J, Cruz F, et al.: EAU Guidelines on Urinary Incontinence in Adults; 2017 [website]: https://uroweb.org/wp-content/uploads/EAU-Guidelines-Urinary-Incontinence-2016.pdf; pp 60–61.)

Conclusion

UI in men can be related to a number of conditions. It is important to assess these patients appropriately to formulate a management plan that will help improve the patient's QoL. Depending on the cause, initial treatment is usually conservative and medical, with surgical therapies reserved for those who fail initial treatment and in whom the UI is affecting their QoL.

Urodynamic and Video-Urodynamic Evaluation of the Lower Urinary Tract

---

Benjamin M. Brucker MD, Victor W. Nitti MD

Dysfunction of the lower urinary tract may result in a variety of lower urinary tract symptoms (LUTS) that can have a significant negative effect on quality of life. In addition, lower urinary tract dysfunction can be “silent” with no symptoms but can place a person at risk for upper tract deterioration. **Urodynamic studies (UDS) use a set of measurements to assess the function and dysfunction of the lower urinary tract** (Rosier et al., 2017a). UDS are often useful to diagnose suspected lower urinary tract dysfunction and also to assess the effects of known lower urinary tract dysfunction. The lower urinary tract has two essential functions: the storage of urine at low pressure and the voluntary evacuation of urine. Low-pressure storage is essential to protect kidneys and ensure continence, and voluntary evacuation allows for the elimination of urine in socially acceptable situations without fear of leakage or overdistension. It is clear that a number of conditions and diseases affect the lower urinary tract and disrupt the storage and/or evacuation of urine. This can lead to bothersome symptoms (e.g., urinary frequency, urgency and incontinence, slow or interrupted stream) or, in some cases, potentially harmful sequela (e.g., urinary tract infection, renal failure). In some cases, a precise assessment of storage and emptying is necessary to optimize patient treatment(s). UDS are composed of a number of dynamic tests that are individually or collectively used to gain information about the transport, storage, and evacuation of urine. UDS involve the assessment of the function and dysfunction of the urinary tract and includes the actual tests that are performed (UDS studies) and the observations during the testing (UDS observations) (Abrams et al., 2002).

The principles of urodynamics and the technical performance and interpretation of urodynamic studies have not changed much over the last several editions of this book.

Video 114.1 demonstrates some of the basics of urodynamics, in this case for women with pelvic floor dysfunction. What has changed is the widespread use of clinical guidelines. Some urodynamic-specific guidelines exist (Winters et al., 2012) that **“intended to assist the clinician in the appropriate selection of urodynamic tests, following evaluation and symptom characterization.”** However, there has also been a trend to include UDS in disease-specific guidelines, for example, neurogenic lower urinary tract dysfunction (NLUTD), urinary incontinence, stress incontinence, and overactive bladder (Kobashi et al., 2017; Lucas et al., 2013; Pannek et al., 2013). This chapter incorporates the current available literature and guidelines recommendation. It also places emphasis on the practical use and clinical utility of UDS and how they apply to specific conditions of the lower urinary tract. Some of the basics of urodynamics are illustrated in Video 114.1.

Urodynamic principles, equipment, and performance details apply to both adults and children. This chapter is limited to discussion of UDS in specific conditions to adults. Many of the conditions for which UDS is used in children involve anatomic and neurologic abnormalities in which lower urinary tract function is variable and unpredictable. UDS is used to establish as clearly as possible the baseline situation so that changes as a result of treatment and/or growth can be assessed and some guidance is obtained in the choice of treatment, even if the result of UDS testing is not necessarily the deciding factor (Hosker et al., 2009). In the pediatric population, the aim of UDS is not only to provide precise knowledge of lower urinary tract function, but also to provide an understanding of the current and future condition to the caregiver and patient (and his or her parents). Of course, it is still imperative that the testing should be relevant, reliable, and reproducible. The reader is referred to Chapter 28 for a more detailed discussion of specific conditions in children.

Role of Urodynamics in Clinical Practice

UDS have been used for decades, yet level 1 evidenced-based “indications” for its use are limited. There are myriad reasons for the evidence being sparse. It is difficult to conduct proper randomized controlled trials on UDS for conditions when lesser levels of evidence and expert opinion strongly suggest clinical utility and when “empiric treatment” is potentially harmful or even life-threatening (e.g., NLUTD). Additionally, symptoms can be caused by a number of different conditions, and it is difficult to study pure or homogeneous patient populations. High-level data looking at the role of UDS in counseling patients and the patient perception of the shared decision-making process before intervention is also not available. Further, data looking longitudinally at UDS findings to predict the most cost-effective evaluation methods and treatment options (e.g., who would benefit from early surgical intervention of bladder outlet obstruction [BOO] secondary to BPH) require complex modeling with accurate point estimates or expensive long-term studies (Bosch et al., 2011). However, two trials provide some level 1 evidence for the use of UDS before surgery in women with stress urinary incontinence (SUI) (Nager et al., 2012; van Leijsen et al., 2013). **Given the current state of evidence for UDS, what is most important is that the clinician has clear-cut clinical questions to answer by performing the study. This information obtained will be used to guide treatment and/or follow-up.**

In practical terms, UDS is most useful when history, physical examination, and simple tests are not sufficient to make an accurate diagnosis and/or institute treatment. This has clinical applicability in two general scenarios:

- To obtain information needed to make an accurate diagnosis for what condition(s) is causing symptoms (e.g., lower urinary tract symptoms or urinary incontinence).
- To determine the impact of a disease that has the potential to cause serious and irreversible damage to the upper and lower urinary tract (e.g., neurologic diseases such as spinal cord injury and multiple sclerosis, radiation cystitis). Sometimes profound abnormalities can be found in the relative absence of symptoms.

Rather than refer to a list of “indications for UDS” that often are all evidence-based, it is more useful for clinicians to think of how UDS should be used in a broader clinical perspective. In keeping with this theme, the role of UDS in clinical practice has been nicely summarized by Rosier et al. for the following situations (Rosier et al., 2017a):

- To identify or rule out factors contributing to lower urinary tract dysfunction (e.g., urinary incontinence) and assess their relative importance
- To obtain information about other aspects of lower urinary tract function or dysfunction whether or not expressed as a symptom or a recognizable sign
- To allow a prediction of the possible consequences of lower urinary tract dysfunction for the upper urinary tract (see Box 114.1 for UDS findings that are risk factors for upper tract decompensation)

Box 114.1

Urodynamic Risk Factors

The following UDS findings are potentially dangerous and usually require intervention to prevent upper and lower urinary tract decompensation:

1. Impaired compliance
2. Detrusor–external sphincter dyssynergia (DESD)
3. Detrusor–internal sphincter dyssynergia (DISD)
4. High-pressure detrusor overactivity present throughout filling
5. Elevated detrusor leak point pressure (>40 cm H_2O)
6. Poor emptying with high storage pressures

- To allow a prediction of the outcome, including undesirable side effects, of a contemplated treatment
- To confirm the effects of intervention or understand the mode of action of a particular type of treatment for lower urinary tract dysfunction, especially a new and/or experimental (not routine)

one
- To understand the reasons for failure of previous treatments for urinary incontinence or for lower urinary tract dysfunction in general (after unsatisfactory treatment)

It is important to remember that UDS is only one part of the comprehensive evaluation of symptoms and lower urinary tract function, and when it is done to investigate a patient's symptoms, the goal of the study is to reproduce the symptoms and determine the cause by urodynamic measurements or observations. To use UDS in a practical and effective way, it is important that the clinician has the proper expertise to know when and why to perform UDS. Despite many technical advances in the recording, processing, and printing of UDS, careful attention to technical details to assure accurate collection of data remains the cornerstone of a good study. Because not all patients undergo UDS for the same reasons, the clinician should “customize” UDS to the patient's symptoms and condition. This means deciding on the questions to be answered before starting each study and designing the study to obtain answers to those questions. It is important to remember that UDS are performed in an “unnatural setting” and therefore do not always duplicate real-life situations. A UDS that does not duplicate complaints or symptoms when an abnormality is recorded is not necessarily diagnostic. In addition, failure to record an abnormality does not always rule out its existence (e.g., failure to demonstrate detrusor overactivity in a patient with urgency incontinence). Finally, not all UDS observations are clinically significant. Therefore, it is important to interpret UDS in the context of the patient's history, including symptoms and concomitant diseases/conditions and other information like postvoid residual volumes and frequency volume charts (voiding and intake diaries) when clinically applicable.

Key Points

- Urodynamics is the dynamic study of the transport, storage, and evacuation of urine.
- UDS is composed of a number of tests that individually or collectively can be used to gain information about urine storage and evacuation.
- Guidelines are intended to *assist* the clinician to select appropriate

urodynamic tests after evaluation and symptom characterization.

Conducting a Urodynamic Study: Patient and Technical Factors

Functional Classification of Voiding Dysfunction

Perhaps the most important concept to understand when trying to set up, conduct, or interpret a UDS is the Functional Classification of Voiding Dysfunction, popularized by Wein (1981). This practical classification is a simple way of thinking about a complex subject of voiding dysfunction. It allows one to classify dysfunction of the lower urinary tract according to urodynamic findings. **Functionally, abnormalities of the lower urinary tract can be divided into the following:**

- Storage dysfunction (failure to properly store urine)
- Emptying dysfunction (failure to empty the bladder normally)
- Combined dysfunction (failure to store and empty)

In addition, functional abnormalities can be subclassified to the anatomic region of the lower urinary tract that is affected and how it is affected. Thus, storage and emptying abnormalities can be caused by the following:

- Bladder dysfunction: Overactive (causing failure to store) or underactive (causing failure to empty)
- Bladder outlet dysfunction: Overactive (causing failure to empty) or underactive (causing failure to store)
- Combined bladder and bladder outlet dysfunction

Keeping this system in mind allows the clinician to formulate a set of questions to be answered by the UDS and gives an understanding of the possible causes of symptoms or findings before starting the test. The other advantage of the functional classification system is that it helps organize the treatment options for a given patient. Thus, in practical terms, the UDS evaluation should help determine if there is bladder or bladder outlet dysfunction (or both) and whether there is a storage and/or emptying problem. Finally, when the study provides the answers, UDS can lead to a correct diagnosis and institution of appropriate treatment. Obviously, an understanding of the physiology of urine storage and voiding and the pathophysiology of voiding dysfunction (see Chapter 111) is required to formulate appropriate questions to be answered by a UDS. This simple classification can prevent a clinician from getting caught up in the intricate neurophysiologic aspects of voiding and storage dysfunction, failing to think in practical terms. One should always focus on the possible urodynamic findings in a given case and how each of the findings may ultimately affect the patient and his or her treatment. Symptoms and/or underlying conditions or diseases will determine these potential findings.

Preparing for Urodynamic Studies: Clinician, Patient, and Facility

Defining the Clinical Question

A list of problems or questions that should be solved or answered by UDS should be made before any invasive UDS is performed. All patients are not alike, and therefore each urodynamic evaluation may be different depending on the information needed to answer the questions relevant to a particular patient. **Three important rules before starting the UDS evaluation include the following** (Nitti and Combs, 1998):

- Decide on questions to be answered before starting a study.
- Design the study to answer these questions.
- Customize the study as necessary.

The simple fact that a patient has symptoms or a disorder that may affect the lower urinary tract is not sufficient to start the UDS evaluation. It is imperative to decide on what information needs to be obtained for a UDS before starting it. This will vary from patient to patient. It is also important to consider expert opinion (MacLachlan and Rovner, 2014), history, medication use, and physical examination before performing UDS. Many patients undergoing urodynamic testing will have been placed on medications that can affect bladder function (e.g., antimuscarinics). For such patients, the clinician should decide in advance what information is desired and whether or not the study should be done on or off medication. For example, if the goal of the study is to determine the therapeutic effect of a medication, obviously the UDS should be done with the patient on a regular dosing schedule for that medication. On the other hand, if medication was started empirically to treat symptoms and the goal of the urodynamic test is to uncover the etiology of those symptoms, then consideration can be given to discontinuing the medication before testing as this may give the highest yield. The medication used and status should also be documented.

Further, the International Continence Society (ICS) suggested that a validated symptom and bother score be obtained in addition to a 3-day frequency volume chart or bladder diary, and, finally, noninvasive measures such as a uroflowmetry and PVR. These tests inform the clinician of the most relevant clinical data before invasive testing is performed. An example of this would be the pre-UDS normal noninvasive flow rate and low PVR data allowing for the appropriate interpretation of an abnormal flow rate during invasive UDS as likely artefactual.

Patient Preparation

Patients should be properly prepared and told why the test is being done, how the results may affect treatment, and what to expect during the actual UDS. Studies have shown that UDS are generally well tolerated. Scarpero et al. (2005) used a questionnaire-based study to assess patient expectations of anxiety, pain, embarrassment, and apprehension before UDS and compared it with the patient's actual experience. They found that UDS was associated with minimal to moderate degrees of anxiety, discomfort, and embarrassment. After testing, most respondents (greater than 90% per question) thought that the test was the same or better than expected and it was associated with an expected or less than expected level of pain and embarrassment. This did not vary between the sexes, but a higher number of younger individuals found that the test experience was worse than expected, and a higher number of older individuals found that it was better than expected. Younger age has been found in other studies to portend higher pain and anxiety during UDS (Yeung et al., 2014; Yiou et al., 2013). Therefore, younger patients may require more reassurance and attention in preparation for the procedure. Similarly, Yokoyama et al. (2005) found UDS to be quite tolerable based on a questionnaire study. Patients experienced minimal degrees of pain, embarrassment, and physical burden from UDS. On a visual analog pain scale of 0 to 10 (*not at all* to *unbearable*) in 154 consecutive patients (56% men), the mean (SD) degrees of pain, embarrassment, and physical burden were 2.27 (2.53), 2.59 (2.69), and 1.76 (2.43), respectively, and 73.6% of men and 80.6% of women were willing to repeat the UDS. The most common complaint after UDS was micturition pain. Urinalysis showed that 4.6% of men and 7.5% of women had leukocyturia after the investigation. A prospective study recently evaluated the effect of dimmer lighting and audio distraction (instrumental music) in a mostly Hispanic female cohort undergoing UDS (Rezvan et al., 2017). Though not significant, the underpowered study trended strongly toward a clinically meaningful reduction in embarrassment and anxiety with inexpensive, readily available interventions.

Some populations of patients may not understand the role or purpose of UDS (Smith et al., 2011). Patient dissatisfaction with care may be affected if there is poor communication and understanding of diagnostic tests. However, prospective studies aimed at educating patients with an “explanatory pamphlet” have been largely disappointing (Hougardy et al., 2009; Bright et al., 2011). We therefore often rely on our staff. Well-trained, attentive, and supportive staff can be very helpful in ensuring that the patient has the best possible experience and is getting a good-quality study.

Best practice recommends that a urinalysis should be performed on all patients before invasive UDS (level 4 evidence) (Cameron et al., 2017). Further, in patients with a symptomatic UTI, urodynamics should be delayed until the patient completes treatment. The American Urological Association (AUA) Best Practice Policy (BPP) Statement on Urologic Surgery Antimicrobial Prophylaxis states that prophylactic antibiotics are not routinely indicated before UDS for patients without UTI risk factors (also called “index” patients) (Wolf et al., 2008). However, it is common for UDS to be performed on more complicated patients. Patients often have known or suspected abnormalities of the urinary tract. The Society of Urodynamics, Female Pelvic Medicine and Urogenital Reconstruction (SUFU) convened a Best Practice Policy Panel to formulate recommendations on the use of antimicrobial prophylaxis during UDS for the prevention of UTIs, with special attention aimed at patients who fall outside of the “index” patient. This paper suggests that patients who require antibiotic prophylaxis should receive a single dose within 1 hour before UDS. Oral trimethoprim/sulfamethozaxole is the first option, with acceptable alternatives including a first- or second-generation cephalosporin, amoxicillin/clavulanate, or intravenous aminoglycoside ± ampicillin and fluoroquinolones (level 3 evidence). Table 114.1 shows risk factors and recommendation of antibiotic use alone with level of evidence.

TABLE 114.1

Risk Factors and Recommendations for Antibiotics Before Invasive Urodynamic Studies

RISK FACTOR	RECOMMENDATION FOR ANTIBIOTICS	LEVEL OF EVIDENCE
Recommendations concerning pre-procedure urine testing Urinalysis should be performed on all patients before urodynamic study.	All patients need urinalysis, if positive and no urinary tract infection, need prophylaxis	4
Patients with current urinary tract infection In patients with a symptomatic urinary tract infection, urodynamic studies should be delayed until the patient completes treatment.	Cancel urodynamic studies until urinary tract infection treated	4
Patients with presumed normal genitourinary anatomy *Antibiotic prophylaxis is not recommended for urodynamic studies in patients with normal genitourinary anatomy and no risk factors*. The presence of an abnormality discovered during urodynamic studies that is a risk factor warrants antibiotic prophylaxis to be given immediately after the study.	No	1
Patients with neurogenic lower urinary tract dysfunction Antibiotic prophylaxis is recommended for urodynamic studies in patients with neurogenic lower urinary tract dysfunction.	Yes	4
Patients with bladder outlet obstruction and/or elevated postvoid residual Antibiotic prophylaxis is recommended for urodynamic studies in patients with clinically important elevated postvoid residual, regardless of the cause.	Yes	4
Advanced age (older than 70 years) Antibiotic prophylaxis is recommended for urodynamic studies in patients older than	Yes	2

70 years.		
Diabetes mellitus Antibiotic prophylaxis is not recommended for urodynamic studies in the presence of diabetes.	No	4
Recent prolonged hospitalization Antibiotic prophylaxis is not recommended for urodynamic studies in the presence of a recent prolonged hospitalization in the absence of other risk factors.	No	4
Diet and nutrition Antibiotic prophylaxis is not recommended for urodynamic studies in the presence of dietary or nutritional deficiencies including obesity.	No	4
Menopausal status Antibiotic prophylaxis is not recommended for urodynamic studies based on menopausal status.	No	2
Asymptomatic bacteriuria Antibiotic prophylaxis is recommended for urodynamic studies in patient with asymptomatic bacteriuria.	Yes	4
History of recurrent urinary tract infections Antibiotic prophylaxis is not recommended for urodynamic studies in patient with a history of recurrent urinary tract infections.	No	4
Gender Antibiotic prophylaxis is not recommended for urodynamic studies based on gender.	No	4
Immunosuppression, corticosteroids, and inherent immune deficiency Antibiotic prophylaxis is recommended for urodynamic studies in patients with immunosuppression from immunosupressants, chronic steroids, or innate immunosuppression, particularly those who have had renal transplant.	Yes	4
Patient with chronic catheters Antibiotic prophylaxis is recommended for urodynamic studies in patients with	Yes	4

indwelling urinary catheters (either urethral or suprapubic), external condom catheters, or those performing CIC.		
Prior urologic surgery Antibiotic prophylaxis is not recommended for urodynamic studies in the presence of a history of prior urologic surgery.	No	4
Cardiac valvular disease Antibiotic prophylaxis should not routinely be administered for urodynamic studies in the presence of cardiac valvular disease.	No	3
Orthopedic implant Antibiotic prophylaxis is recommended for patients undergoing urodynamic studies who have had total joint implant and who are at increased risk for developing joint infection from bacteremia or have an increased risk for actually developing bacteremia.	Yes	3

From Cameron AP, Campeau L, Brucker BM, et al. Best practice policy statement on urodynamic antibiotic prophylaxis in the non-index patient. *Neurourol Urodyn* 36:915–926, 2017.

Facility Setup

In addition to other technical aspects of UDS, the room setup is also important. Ideally, a room of suitable size should be dedicated to urodynamics (Nitti and Combs, 1998). This area does not have to be exclusively for urodynamics, but when a study is being performed, there should be no distractions from people walking into and out of the area for other reasons. A quite private area is the best. It is difficult enough to recreate a natural environment during testing without outside distractions. The room should be large enough to allow for the patient to lie down to have catheters placed and also to stand and sit on a commode as necessary. Many patients undergoing UDS may have concomitant neurologic conditions that limit or alter mobility, requiring assistance with positioning. The need for wheelchairs, walkers, scooters, and even lifts must be considered when determining the size of the room. Centers that perform videourodynamics will require a larger area to allow for fluoroscopic equipment. There may be local or institutional regulations regarding fluoroscopy that should be consulted as well.

Special equipment may be needed, and ensuring that it is available before starting the study can ensure that the test is done in the way most likely to yield data to answer the clinical question(s). Pessary kits, scopetts, and speculums may be needed if testing is done on women with pelvic organ prolapse. A simple stepstool can be helpful to obtain voiding images of the male urethra or to visualize the female urethra if the patient is standing for stress maneuvers and the c arm has a limited minimal high. Large catheters to drain the bladder may be useful if the pre-invasive UDS workup suggests very elevated PVR.

Additional Factors

By following these simple rules, one can maximize the chance of obtaining useful information from an invasive UDS. If a particular question is not answered, the study can be repeated in the same or a later session. Many authors utilize or advocate a second filling and/or voiding cycle, especially if questions remain unanswered (Bellucci et al., 2012; Broekhuis et al., 2010; Brucker et al., 2016). Even with multiple cycles and utilizing best practices (Rosier et al., 2017a), UDS do not always answer all of the important questions. But, by clearly defining the information needed before starting the study, unanswered questions can be kept to a minimum. We cannot emphasize enough that one of the most important parts of UDS is its proper performance with careful attention to technical details so that accurate interpretation is possible. It is beyond the scope of this chapter to describe the proper performance of UDS in detail; however, the reader is referred to Rosier et al. (2017b) for updated good urodynamic practices and terminology. Two other comprehensive works are frequently referenced in this update and round out the terminology and good practice details (Abrams et al., 2002; Schafer et al., 2002). The ICS defined the term *urodynamic observations* to denote those observations that occur during and are measured by the UDS test itself (Abrams et al., 2002). To be consistent, it is recommended that all clinicians performing and interpreting UDS use the current ICS terminology. Clinically, this terminology can help ensure that reporting is consistent and that the ensuing interpretation is understood by others. A list of common UDS terms is provided in Box 114.2.

Box 114.2

Terminology for Common Urodynamic Terms and Observations According to the International

Continence Society Standardization Sub-Committee

Included are common definitions that have not been changed from Abrams et al. (2002) and new definitions from Roiser et al. (2017) ICS, as indicated with an asterisk. To be consistent, it is recommended that all clinicians performing and interpreting UDS use the current ICS terminology.

Terminology for Common Urodynamic Terms and Observations According to the International Continence Society Standardization Subcommittee

In 2002, the ICS defined the term *urodynamic observations* to denote observations that occur during and are measured by urodynamics (UDS). They also attempted (and continue to attempt) to define terminology that all clinicians performing and interpreting UDS can use (Abrams et al., 2002). The most recent work (Rosier et al., 2017b) has continued to refine and newly define other terminology. This body of terminology is considered the “ICS standard.” It should be considered “Best practice, based on evidence, with the use of standard terms and standard techniques, evaluated and reported clinically or scientifically, in a complete and validated manner.” In certain cases, and/or in research studies, individuals may elect not to adhere to this standard, but should then specify any deviations. An asterisk represents a new definition.

Definitions of Study Types

Urodynamics: The general term to describe all measurements that assess the function and dysfunction of the LUT by any appropriate method. Urodynamics allow direct assessment of LUT function by the measurement of relevant physiologic parameters.

Invasive urodynamics: Any test that is invasive, as it involves insertion of one or more catheters or any other transducers into the bladder and/or other body cavities, or insertion of probes or needles, for example for EMG measurement.

Noninvasive urodynamics: All urodynamics done without the insertion of catheters: for example, uroflowmetry, PVR, penile compression-release test, penile cuff, urethral connector, condom catheter, or sonography.

Ambulatory urodynamics: A functional test of the lower urinary tract using natural filling and reproducing the subject's everyday activities (see van Waalwijk van Doorn et al., 2000).

ICS standard urodynamics protocol*: A patient undergoing collection of a clinical history (should include a valid symptom and bother score(s) and a medication list), relevant clinical examination, 3-day bladder diary, representative uroflowmetry with postvoid residual (PVR), and a complete ICS standard urodynamic test (see the following) is referred to as having had the "ICS standard urodynamics protocol (ICS-SUP)."

ICS standard urodynamic tests*: Uroflowmetry and PVR plus transurethral cystometry and pressure-flow study (see below): all tests are performed in the patient's preferred or most usual position: comfortably seated and/or standing, if physically possible. The patient(s) is reported as having had an ICS standard urodynamic test (ICS-SUT).

ICS supplementary urodynamic tests: ICS-SUT may be supplemented with EMG, with imaging, with continuous urethral pressure(s), and/or with urethral pressure profile measurement. Cystometry may be done via a suprapubic catheter (specify supplements).

Definitions of Common Values and Measures During or Interpreted After Invasive UDS

Intravesical pressure (p_{ves}): The pressure within the bladder.

Abdominal pressure (p_{abd}): The pressure surrounding the bladder; currently it is estimated from rectal, vaginal, or extraperitoneal pressure or a bowel stoma.

Detrusor pressure (p_{det}): The component of intravesical pressure created by forces on the bladder wall that are both passive and active. It is estimated by subtracting abdominal pressure from intravesical pressure.

Initial resting pressure*: p_{ves} and p_{abd} pressure at the beginning of the cystometry.

Physiologic filling rate: A filling rate less than the predicted maximum. Predicted maximum is the body weight in kilograms divided by 4 and expressed as milliliters per minute (typically in the range of 20 to 30 mL/min).

Nonphysiologic filling rate: A filling rate greater than the predicted maximum (commonly used).

Cough pressure peak*: A cough pressure peak is recognizable during posttest evaluation as a phasic positive pressure change observed in p_{ves} and in p_{abd}.

Position change*: A change in patient position, either active or passive (e.g., tilting), is visible on the cystometry trace by a lasting change of equal magnitude in both p_{ves} and p_{abd}.

Rectal contractions*: Rectal contractions are temporary phasic increases in p_{abd} without synchronous change in p_{ves} resulting in negative deflections of p_{det}.

Definitions of Bladder Sensations and Storage Observations

Normal bladder sensation: Judged by three points noted during filling cystometry and evaluated in relation to the bladder volume at that moment and in relation to the patient's symptomatic complaints. First sensation of bladder filling: the volume at which the patient first becomes aware of the bladder filling. First desire to void: the feeling during filling cystometry that would lead the patient to pass urine at the next convenient moment. Strong desire to void: a persistent desire to void without the fear of leakage. (Note: a visual analog scale is not suggested as a standard.*)

Increased bladder sensation: Early bladder sensation that occurs at low bladder volumes and persists.

Reduced bladder sensation: Diminished sensation throughout bladder filling.

Absent bladder sensation: No bladder sensation. Nonspecfic bladder sensation: the individual is aware of bladder filling because of other sensations such as abdominal fullness or vegetative symptoms.

Bladder pain: A self-explanatory term that is abnormal.

Urgency: A sudden compelling desire to void.

Cystometric capacity: The bladder volume at the end of the fillling cystogram when permission to void is given.

Maximum cystometric capacity: The volume at which the patient feels he or she can no longer delay micturition and has a strong desire to void.

Normal urethral closure mechanism: This maintains a positive urethral closure pressure during bladder filling, even in the presence of increased abdominal pressure.

Incompetent urethral closer mechanism: This is defined as one allowing leakage of urine in the absence of detrusor contraction.

Urethral relaxation incontinence: Leakage related to urethral relaxation in the absence of raised abdominal pressure or detrusor overactivity.

Urodynamic stress incontinence: The involuntary leakage of urine during increased abdominal pressure in the absence of a detrusor contraction.

Urodynamic stress test*: Any physical effort of the person tested, to elevate abdominal pressure during cystometry, with the aim of examining (urodynamic) SUI.

Leak point pressure*: The leak point pressure (LPP) is the pressure (spontaneous or provoked) that has caused fluid to be expelled from the bladder at the moment that it is visible outside the urethra (may also be used for extraurethral urine loss or stoma). This may refer to abdominal, cough or Valsalva, or detrusor LPP.

Definitions Related to Detrusor Function During Invasive UDS

Detrusor overactivity: Involuntary detrusor contractions during the filling phase, spontaneous or provoked. Phasic detrusor overactivity: a characteristic waveform that may or may not lead to urinary incontinence.

Terminal detrusor overactivity: A single involuntary detrusor contraction occurring at cystometric capacity that cannot be suppressed, resulting in incontinence with bladder emptying.

Detrusor overactivity incontinence: Incontinence related to involuntary detrusor contractions. This may be qualified according to cause.

Neurogenic detrusor overactivity: Overactivity accompanied by a neurologic condition.

Idiopathic detrusor overactivity: Detrusor overactivity without concurrent neurologic etiology.

Provocative maneuvers: Techniques used during urodynamic border to provoke detrusor overactivity.

Cough-associated detrusor overactivity*: When the onset of the detrusor overactivity (with or without leakage) occurs immediately after the cough pressure peak.

Bladder outflow obstruction (BOO) ("outflow" to recognize what is

measured)*: A (specified) cutoff of bladder outflow resistance based on the pressure-flow relation (ratio) that is considered clinically relevant.

Normal voiding function*: Flow rate (and pressure-rise) are within normal limits; begin more or less directly after permission to void, and end with an empty bladder.

Situational inability to void and situational inability to void as usual*: When, in the opinion of the person performing the test, in communication with the patient, the attempted voiding has not been representative.

Detrusor voiding contraction*: For any analysis of combined pressure and flow (± other variables) that qualifies or quantifies the actual observed voiding.

Detrusor contractility*: Any method that aims to quantify “intrinsic” detrusor muscle properties (e.g., potential-maximum-force or velocity) by any method

Normal detrusor function: Allows bladder filling with little or no change in pressure and no involuntary contractions despite provocative maneuvers.

Dropped p_{abd} at void*: A drop in p_{abd} during voiding is reported during the voiding time, p_{abd} decreases below the previous resting pressure (as a consequence of pelvic and abdominal muscle relaxation).

Straining*: Straining is observable as a temporary increase in both p_{ves} and p_{abd} pressure. Straining may be associated with (patient-active) position change (such as repositioning from leaning backward to upright).

After-contraction*: A continued or new detrusor pressure rise immediately after flow ended. It is important to note if this occurs with the complete emptying of the bladder.

Urethral Pressure Measurements

Urethral pressure: The fluid pressure needed to just open a closed urethra.

Urethral pressure profile: A graph indicating the intraluminal pressure along the length of the urethra.

Urethral closure pressure profile: The subtraction of intravesical pressure from urethral pressure.

Maximum urethral pressure: The maximum pressure of the measured profile.

Maximum urethral closure pressure (MUCP): The maximum difference between the urethral pressure and the intravesical pressure.

Functional profile length: The length of the urethra along which the urethral pressure exceeds intravesical pressure in women.

Pressure transmission ratio: The increment in urethral pressure on stress as a percentage of the simultaneously recorded increment in intravesical pressure.

Abdominal leak point pressure: The intravesical pressure at which urine leakage occurs because of increased abdominal pressure in the absence of a detrusor contraction.

Detrusor leak point pressure: The lowest detrusor pressure at which urine leakage occurs in the absence of either a detrusor contraction or increased abdominal pressure.

Pressure-flow studies: The method by which the relationship between pressure in the bladder and urine flow rate is measured during bladder emptying.

Premicturition pressure: The pressure recorded immediately before the initial isovolumetric contraction.

Opening pressure: The pressure recorded at the onset of urine flow.

Opening time: The elapsed time from original rise in detrusor pressure to onset of flow.

Maximum pressure: The maximum value of the measured pressure.

Pressure at maximum flow: The lowest pressure recorded at maximum measured flow rate.

Closing pressure: The pressure measured at the end of measured flow.

Minimum voiding pressure: The minimum pressure during measurable flow.

Flow delay: The time delay between a change in bladder pressure and the corresponding change in measured flow rate.

Definitions Related to Artifacts of Invasive Urodynamics

Dead signal*: A signal that is not showing small pressure fluctuations and is not adequately responding on straining, patient movement, or coughing.

Pressure drift*: Continuous slow fall or rise in pressure that is physiologically inexplicable.

Poor pressure transmission*: When the cough/effort pressure peak signals on p_{ves} and p_{abd} are not nearly equal.

Expelled catheter*: When a catheter is expelled, this is observed as a sudden drop in either p_{ves} or p_{abd}, usually below zero.

Catheter flush*: When one of the catheters is flushed during the test, a steep pressure rise is observed in that pressure line for one or two seconds followed by an immediate fall to resting pressure.

Tube knock*: Observable as high-frequency, short-duration spikes visible in p_{ves}, p_{abd}, or both and with spikes also usually visible in p_{det}.

Pump vibrations*: Pump vibrations are visible as stable frequency oscillations of small but constant amplitude if the filling tube touches the pressure connecting tube (when a two-catheter system is used) and the pump is switched on (switching of the pump can ascertain the situation).

Data from Abrams P, Cardozo L, Fall M, et al. The standardization of terminology of lower urinary tract function: report from the Standardization Subcommittee of the International Continence Society. *Neurourol Urodyn* 21:167–178, 2002; Schafer W, Abrams P, Liao L, et al. Good urodynamic practices: uroflowmetry, filling, cystometry, and pressure-flow studies. *Neurourol Urodyn* 21:261–274, 2002; Rosier PFWM, Schaefer W, Lose G., et al. International Continence Society Good Urodynamic Practices and Terms 2016: Urodynamics, uroflowmetry, cystometry, and pressure-flow study. *Neurourol Urodyn* 36(5):1243–1260, 2017.

The ICS has also published updated condition-specific terminology references for female pelvic floor dysfunction and adult neurogenic patients, which may include additional terminology (Gajewski et al., 2017; Haylen et al., 2010).

Components of the Urodynamic Study

Before discussing the details of the UDS, it is useful to be familiar with the different components of the test. These tests within the study can be used individually or in combination, depending on the information desired. For the purposes of this chapter, we will discuss each component as part of the entire multichannel UDS or video UDS (VUDS). Uroflow and postvoid residual (PVR) determination are two simple, noninvasive tests that can be used to evaluate voiding function and perhaps prompt further testing. In addition, both are part of a multichannel UDS.

Postvoid residual is an excellent assessment of bladder emptying. It can be performed by ultrasonography (bladder scan) or catheterization (method should be specified). Elevation of PVR indicates a problem with emptying but does not tell why. An elevated PVR may prompt further testing. In cases when PVR is elevated, it should be confirmed with a second measurement, especially for situations in which a patient did not have a true desire to void before PVR was measured.

Uroflowmetry is measurement of the rate of urine flow over time. It is also an assessment of bladder emptying. There are multiple data points that can be reported from noninvasive uroflowmetry. These include the following:

- Voided volume (VV; mL)
- Flow rate (Q; mL/sec)
- Maximum flow rate (Q_{max}; mL/sec)
- Average flow rate (Q_{ave}; mL/sec)
- Voiding time (total time during micturition; sec)
- Flow time (time during which flow occurred; sec)
- Time to maximum flow (onset of flow to Q_{max}; sec)

Voided percentage (void %) or voiding efficiency is a numerical description of the voiding efficacy or efficiency that is the proportion of bladder content emptied [(volume voided/volume voided + PVR) × 100].

In addition to these objective measurements, it is also important to observe the pattern or shape of the uroflow curve. A normal uroflow curve is bell-shaped (Fig. 114.1). Uroflow curve interpretation is somewhat subjective because of difficulty in qualitatively judging a pattern (Boone and Kim, 1998). When the flow rate is reduced or the pattern is altered, this could indicate dysfunction of the bladder (detrusor underactivity) or bladder outlet (anatomic or functional) (see Fig. 114.1). Although certain patterns are suggestive of certain voiding dynamics (e.g., an interrupted or straining pattern with detrusor underactivity and a flattened pattern with a fixed obstruction), one cannot definitively identify specific underlying abnormalities without detrusor pressure data (see invasive pressure-flow urodynamics later). When done as a standalone test, it may be easiest to optimize patient comfort and reduce anxiety by allowing the patient to perform the voiding in his or her preferred position (e.g., sitting or standing). The patient should also be queried if the urine flow was representative of what occurs during a voiding during nontesting conditions (daily living). Also, the urodynamic voided volume can be compared with frequency volume charts or bladder diary when available. Position of void should be recorded (Gleeson and Lattimer, 1962).

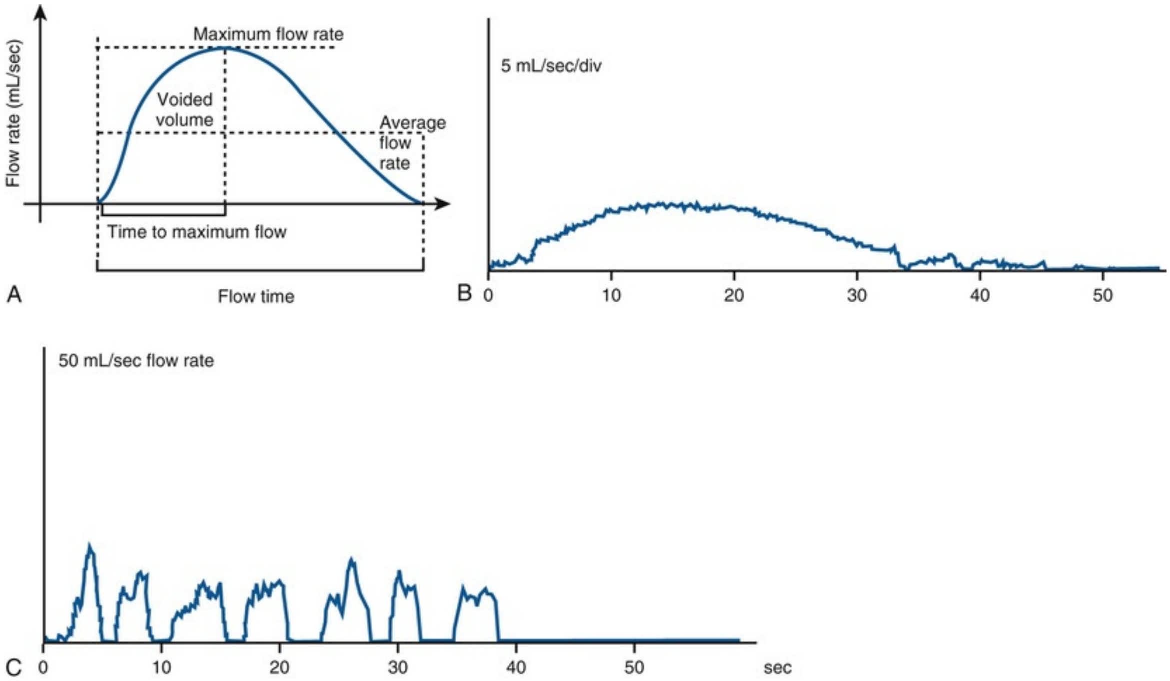

FIG. 114.1 Examples of uroflow curves. (A) normal bell-shaped flow curve of flow rate versus time. (B) flattened pattern usually indicative of obstruction. (C) An interrupted or straining pattern that can be seen with impaired bladder contractility, obstruction, or voiding with or by abdominal straining. (A, from Wein AJ, English WS, Whitemore KE. Office urodynamics. *Urol Clin North Am* 15:609, 1988; B and C, from Boone TB, Kim YH. Uroflowmetry. In Nitti VW, ed. *Practical urodynamics.* Philadelphia,

PA: WB Saunders; 1998:28–51.)

Cystometry or **cystometrogram (CMG)**, or, more appropriately, **filling cystometry** is the method by which the pressure/volume relationship of the bladder is measured during bladder filling. The filling phase starts when filling commences and ends when the patient and urodynamicist decide that "permission to void" has been given (maximum cystometric capacity). Cystometry can be performed by the single measurement of bladder pressure via a bladder catheter (urethral or suprapubic); however, changes in bladder pressure can represent a change in detrusor pressure (p_{det}) or a change in abdominal pressure (p_{abd}) (see later). Therefore, it is recommended that cystometry be performed by measuring both the total vesical pressure (p_{ves}) and p_{abd} (measured by a catheter placed in the rectum or vagina). To calculate detrusor pressure (p_{det}), the following equation is used (Fig. 114.2):

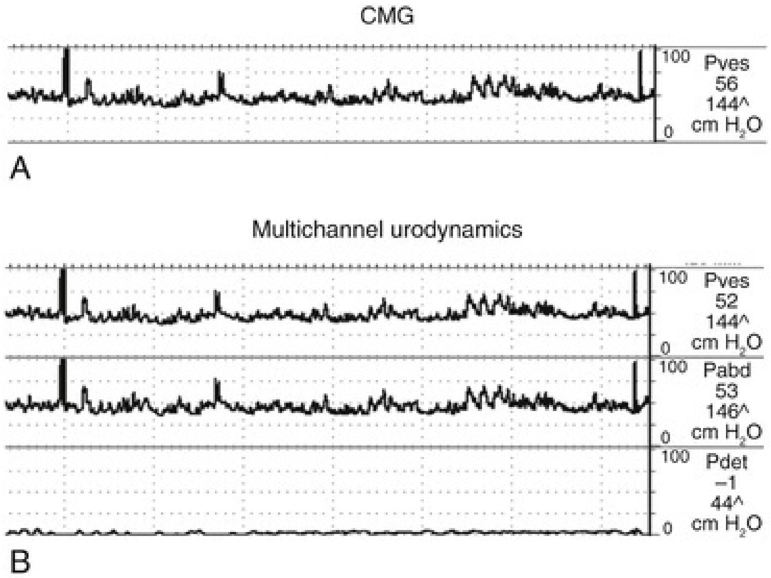

FIG. 114.2 Cystometrogram *(CMG)* measures the pressure in the bladder as the bladder fills over time. Standard fill rates in adults are 30 to 100 cm H_2O per minute. Adding intra-abdominal pressure monitoring gives a better representation of the true detrusor pressure. (A) Single-channel CMG in which only the total vesical pressure *(pves)* is measured. Note the multiple spikes and rises in pressure. Without having simultaneous monitoring of intra-abdominal pressure, it is impossible if these pressure spikes are caused by a rise in detrusor or abdominal pressure. (B) This same tracing with intra-abdominal pressure *(pabd)* monitoring added *(multichannel urodynamics).* This allows for the determination of (subtracted) detrusor pressure *(pdet).* Now it can be clearly seen that changes in pves were

caused by the changes in pabd (e.g., movement, coughing). The pdet curve it is noted to be flat and without any rises in pressure. (From Nitti VW. Cystometry and abdominal pressure monitoring. In Nitti VW, ed. *Practical urodynamics.* Philadelphia, PA: WB Saunders; 1998:38–51.)

$$p_{det} = p_{ves} - p_{abd}$$

Pelvic muscle electromyography (EMG) is the study of the electronic potentials produced by the depolarization of muscle membranes. In the case of UDS, EMG measurement of the striated sphincter muscles of the perineum is done to evaluate possible abnormalities of pelvic floor muscle function, which are often associated with lower urinary tract symptoms and dysfunction. EMG activity is measured during both filling and emptying. ICS standard is now specified as two skin surface electrodes on the perineal surface with an appropriate referent (Rosier et al., 2017b). EMG can also be obtained by vaginal probe (vaginal EMG), anal probe (anal EMG), or needle electrodes (needle EMG).

Urethral pressure profile (UPP) is a graph indicating the intraluminal pressure along the length of the urethra. Urethral pressure is defined as the fluid pressure needed to just open a closed urethra. UPP is obtained by the withdrawal of a pressure sensor (catheter) along the length of the urethra.

Pressure-flow studies (PFS) of voiding are the method by which the relationship between detrusor pressure and urine flow rate is measured during bladder emptying (voiding). Detrusor pressure is measured as noted earlier with the simultaneous measurement of flow rate by a uroflowmeter. The voiding phase starts when “permission to void” is given, or when uncontrollable voiding begins, and ends when the patient considers voiding has finished.

Urodynamic Equipment

Urodynamic Systems

There are a variety of urodynamic systems available today. They range in cost depending on their complexity and the features they contain. Current UDS systems are computer-based digital systems that allow for easy data storage and postprocessing of the study. In addition, they allow for hardware and software upgrades as necessary. It is beyond the scope of this chapter to describe in detail the options available for UDS systems. However, when choosing a system, one must consider the patient population and spectrum of diseases frequently encountered; available space; convenience of operation (if a factor); and the need for data storage and processing and possible electronic medical record integration. In addition, it is recommended that a multichannel system be used where channels are available to measure vesical pressure, abdominal pressure (and subtracted detrusor pressure), and flow rate. Some clinicians may also desire channels for electromyography and urethral pressure measurement. The UDS system and software market is constantly changing, so what is state-of-the-art today may seem “outdated” tomorrow. However, despite all the advances, the clinician performing the study remains the most important constant in data collection and interpretation. For the most realistic assessment, the infusant should be a liquid (e.g., normal saline or radiographic contrast) that most approximates urine. The use of gas, such as carbon dioxide, is not recommended. Many advanced urodynamic centers now perform VUDS. Adding this capability is costly but allows one to perform the most comprehensive study possible. There are certain clinical settings in which VUDS is preferred and may be the “test of choice” (e.g., in advanced NLUTD) (Groen et al., 2016). In addition to the necessary urodynamic hardware and software, a fluoroscopy unit and room of adequate size are required. Obviously, this is not practical or necessary in every setting. VUD studies also require a greater time commitment on the part of the clinician to assure accurate data collection. Thus, VUDS is ideally preformed in centers with a specific interest in complex storage and voiding dysfunction. For specific recommendations regarding UDS equipment performance, the reader is referred to the recently published ICS document on this subject (Gammie et al., 2014).

Signal Transmission and Transducers

Transducers are the hardware that allows pressure in the patient to be measured and transferred to the UDS system. External strain gauge transducers located “between” the patient and the urodynamic machine have been popular for years. Pressurized tubing (to avoid dampening or dissipation of the pressure) extends from the pressure transducer to the catheters placed in the patient. An electronic cable or “wireless transmission” brings the signal from the transducer to the urodynamic machine. Traditionally, a water-filled system was used in which the entire system from transducer to patient is filled with water. Because this system depends on the transmission of pressure through fluid (water), it is crucial that there are no air bubbles in the transducer or tubing. The pressurized tubing transmission lines should be lucent to allow for easy recognition of air in the line. The transducers are usually set at the level of the patient's bladder (symphysis pubis) at the start of the study. This is important because if the patient changes position during the test (e.g., standing to sitting), the height of the transducer can be adjusted so that it remains at the level of the bladder.

More recently **air-charged catheters** (T-Doc, Wenonah, NJ) have become popular for pressure measurement. Air-charged catheters use a miniature, air-filled balloon placed circumferentially around a polyethylene catheter. External forces on the balloon of the catheter are transmitted to the air-filled catheter lumen and communicated to an external semiconductor transducer. The technology of the balloon system allows circumferential measurement readings. The catheters are disposable and intended for single use. Air-charged catheters have several practical advantages over fluid-filled pressure lines because there is no fluid connection between the patient and the urodynamic equipment—just air. This means there is no hydrostatic pressure effect to account for, so there is no need to position anything at the level of the symphysis pubis, and there is no need to flush the system through to exclude air (essential when using a fluid-filled system). Also, there are no artefactual fluctuations in pressure produced when the patient moves. It must also be remembered that **many UDS nomograms and other “standards of measurement” were determined using fluid-filled systems. There is comparative evidence for the use of air-charged catheters to measure urethral pressure** and Valsalva leak point pressure. One study showed comparable performance between air-charged and microtip catheters (Pollak et al., 2004). Another study concluded that they cannot be used interchangeably as air-charged catheters showed systematically higher readings

(Zehnder et al., 2008).

In an experimental model, Cooper et al. showed that **air-charged and water-filled catheters respond to pressure changes in dramatically different ways** (Cooper et al., 2011). Water-filled catheters acted as an underdamped system, resonating at 10.13 ± 1.03 Hz and attenuating signals at frequencies higher than 19 Hz. They demonstrated significant motion and hydrostatic artifacts. Air-charged catheters acted as an overdamped system and attenuated signals at frequencies higher than 3.02 ± 0.13 Hz. They demonstrated significantly less motion and hydrostatic artifacts than water-filled catheters. The authors point out that most urodynamic signals occur below 3 Hz, and, as such, air-charged systems could be beneficial because most of the higher-frequency noise is dampened. However, urodynamic signals can have frequency components greater than 3 Hz, particularly when utilizing rapidly changing signals, such as coughs. The authors concluded that "knowledge of the characteristics of the pressure-measuring system is essential to finding the best match for a specific application."

Two additional studies compared simultaneous pressure values of water-filled systems and air-filled systems during UDS in women (Digesu et al., 2014; Gammie et al., 2016). The studies reported that the systems are not interchangeable because values obtained from each were significantly different. p_{det} values could vary between systems by up to 10 cm H_2O. Pattern analysis was not affected, however, when absolute (subtracted) pressures become relevant (as in pressure-flow analysis or urethral pressure profiles), the possibility of clinically relevant differences exists. Some experts suggest that further validation of measurement techniques with air-filled systems be done before clinical similarity can be established (Abrams et al., 2016).

The conclusions of the 6th International Consultation on Incontinence are that air-charged catheters may provide an acceptable alternative for measuring the closure pressure of the female urethra, however, reference values have not been established (Rosier et al., 2017b). They have not been tested in men, children, or patients with NLUTD. The different catheters record different values and are not interchangeable. Thus, it is recommended that investigators planning to use air-charged catheters for intravesical and intra-abdominal pressure monitoring check for themselves that they have an equivalent performance to their current system for measuring pressure (Rosier et al., 2017).

Finally, a microtip or fiberoptic system can be used to process pressure transmission. Here, the transducer is contained within the catheter. This in turn is connected directly into the urodynamic machine via a cable. These catheters are quite expensive; they are reusable and thus must be sterilized before each use.

Uroflowmeters

Urine flow rate or uroflow can be determined by a number of different types of devices or uroflowmeters. Modern uroflowmeters use weight, electrical capacitance, or a rotating disc to determine urinary flow rates. The two most common techniques used today are the weight transducer or load cell method and the rotating disk method. With the load cell, the voided “weight” is measured and is then differentiated with respect to time to determine the flow rate. In the rotating disc method, the urine stream is directed onto a rotating disc, and the power necessary to keep a disc rotating at a constant rate is measured. This power is proportional to the flow rate. The electronic dipstick flowmeter measures the electrical capacitance of a dipstick mounted in a collecting chamber. The output of the signal is proportional to the accumulated volume, and the volumetric flow rate is determined by differentiation. Each of these methods has advantages and disadvantages. The weight transducer method is simple, reliable, and accurate regardless of the site of stream impact, but it requires that the density of urine be set. The rotating disc method is also reliable and accurate, and it provides a direct measurement without the need for differentiation of volume with respect to time. Electronic flowmeters provide a range of electronically read flow parameters with graphical depiction of the uroflow and have sufficient precision for clinical use with error rates of 1% to 8% in voided volume and 4% to 15% in flow rate (Susset, 1983). Variations in specific gravity of the fluid voided (infusant when doing UDS) can affect the calculated flow rate. Most systems allow for calibrations for various fluids such as radiographic contrast.

Electromyography

Muscle depolarization must be detected by an electrode placed in or near the muscle. Several different methods are available to do this including surface electrodes, needle electrodes, anal or vaginal plug, or urethral catheter mounted electrodes (O'Donnell, 1998). Surface electrodes are self-adhesive skin patch electrodes that are applied over the skin of the anal sphincter (Barrett, 1980). Except in some neurologic diseases, external anal sphincter activity will match external urethral sphincter EMG. Surface electrodes have a significant advantage compared with the needle electrode regarding patient convenience and comfort. However, the surface electrodes provide an inferior signal source and must be precisely placed to provide an adequate signal source. Most clinicians feel that the concentric needle electrode is the superior technique for obtaining a signal source of EMG activity of the striated external sphincter muscles. Compared with the surface electrode, placement of the needle electrode has the disadvantage of being uncomfortable for the patient, especially if more than one attempt at placement of the electrode is required to obtain an adequate signal. Also, the needle electrode is easily dislodged and may require replacement during the study. Patients typically have a low tolerance for replacement of the needle electrode during UDS (Brucker et al., 2012). The performance of an EMG and the selection of the type of electrode to be used are dependent on the UDS question to be answered. EMG recording must also be interpreted in the context of the overall clinical picture of the patient being examined (Khullar et al., 2017).

Key Points

- The functional classification system can help clarify treatment options for a given patient, thus, in practical terms, the UDS evaluation should be performed to help determine if there is bladder or bladder outlet dysfunction (or both) and whether there is a storage and/or emptying problem.
- There should be a clearly defined reason to perform a UDS. The intention should be that the information obtained could be used to guide treatment of the patient.
- UDS is only one part of the comprehensive evaluation of symptoms and lower urinary tract function. The main goal of UDS is to reproduce the patient's symptoms, when present, and determine the cause of these symptoms by urodynamic measurements or observations.
- UDS are interpreted in the context of the patient's history, including symptoms and concomitant diseases/conditions, and other information such as postvoid residual volumes and frequency volume charts (voiding and intake diaries) when clinically applicable.

- Proper urodynamic practices and appropriate terminology should be used when possible.
- Well-trained, attentive, and supportive staff involved with the UDS cannot be overemphasized. Patients should be properly prepared and told why the test is being done, how the results may affect treatment, and what to expect during the actual UDS.

The Urodynamic Study: Analysis and Interpetation

When analyzing and interpreting UDS, it is useful to separate the UDS into filling/storage and voiding phases. This allows for ease of classification of lower urinary tract dysfunction according to the functional classification system mentioned earlier. The filling/storage phase consists primarily of cystometrogram (CMG) and provocative testing (e.g., measurement of abdominal leak point pressure) and urethral pressure measurement during storage. The voiding phase evaluates bladder contractility, bladder outlet resistance, and sphincter coordination by pressure-flow analysis EMG and, in some cases, fluoroscopy.

Filling and Storage Phase

The CMG assesses the bladder's response to filling. The CMG can measure filling pressure, sensation, involuntary contractions (or detrusor activity), compliance, and capacity. Sensation is the part of cystometry that is truly subjective and therefore requires an alert and attentive patient and clinician. The ICS recognizes several subjective parameters that can be recorded during filling (see Table 114.1). Categorizing lower urinary tract sensation during bladder filling (e.g., “urgency” or “early filling sensation”) is now thought to be more clinically important than previously thought. Some treatments are thought to have a specific influence on sensation (de Wachter et al., 2011; Herringa et al., 2011). The end of the CMG is marked by “permission to void” indicated on the urodynamic graph or by stopping the fill pump (however, this may be delayed). End filling should be at a strong but not uncomfortable need to void. A bladder diary or frequency volume chart, along with prior postvoid residual should be considered.

Normal Filling and Storage

Normally, the bladder should store urine at a low pressure and not contract involuntarily. Once capacity is reached or voluntary voiding is desired, intravesical pressure will increase (voluntary detrusor contraction). In actuality, this is preceded by relaxation of the external sphincter. A normalized adult CMG is shown in Fig. 114.3. **Normally detrusor pressure should remain near zero during the entire filling cycle until voluntary voiding is initiated. That means baseline pressure stays constant (and low), and there are no involuntary contractions.** In a terminology guideline for female pelvic floor dysfunction, Haylen et al. (2010) describe this as normal (previously “stable”) detrusor function.

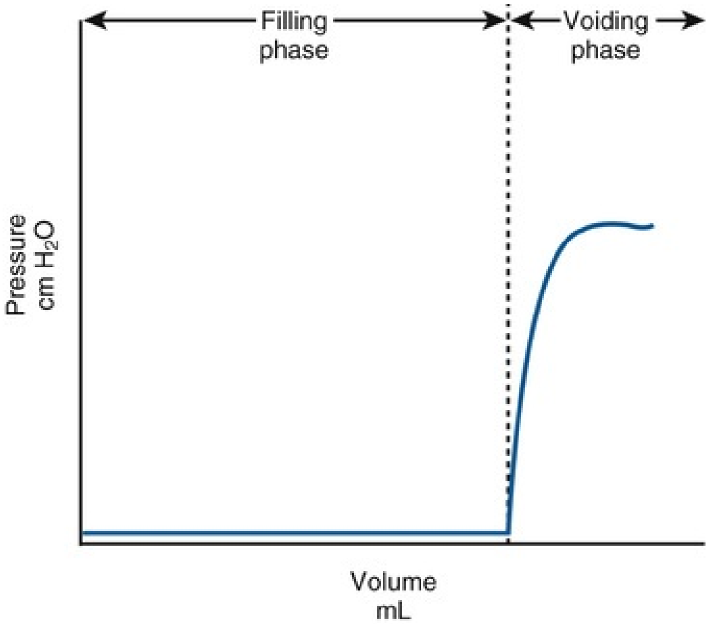

FIG. 114.3 Normal, idealized adult CMG with low-pressure storage until the patient is given the command to void and the voiding phase starts. Note that the baseline bladder pressure is near zero (compliant) and there are no involuntary contractions.

As mentioned earlier, the simultaneous measurement of p_{abd} is done by a rectal, vaginal, or stomal catheter, and p_{ves} during UDS provides a means of calculating the true p_{det}. Data are limited for vaginal and stomal catheter use, and thus a rectal catheter should be used when possible. **The ability to calculate subtracted p_{det} allows one to distinguish between a true rise in detrusor pressure (either via a contraction or loss of compliance) and the effect of increased abdominal pressure** (e.g., straining, Valsalva). This is especially important when rises in detrusor pressure are small or when they are accompanied by changes in abdominal pressure.

Abnormalities of Bladder Filling: Detrusor Overactivity and Impaired Compliance

During filling, involuntary detrusor contractions (IDCs) can occur. These are often associated with urgency and even urgency incontinence. **Detrusor overactivity (DO) is a *urodynamic observation* characterized by IDCs during the filling phase, which may be spontaneous or provoked (Fig. 114.4). DO may be further characterized as *neurogenic DO* when it is associated with a relevant neurologic condition (e.g., spinal cord injury, multiple sclerosis) or *idiopathic DO* when there is "no defined cause" (non-neurogenic)** (Abrams et al., 2002). The term *idiopathic DO* is a bit of a misnomer in that the cause of DO in a non-neurogenic patient may be inferred (e.g., BOO, inflammatory process) or may be truly "unknown." Thus, from a practical standpoint, the terms *neurogenic DO* and *non-neurogenic DO* make more sense but do not fit the ICS definitions. (It should be noted that the term *neurogenic DO (NDO)* replaced the term *detrusor hyperreflexia*, and the term *idiopathic DO* replaced the term *detrusor instability* from older ICS terminology). Neurogenic and idiopathic DO may look identical on CMG. These terms are strictly defined by the patient's neurologic status and not the CMG appearance of the IDCs.

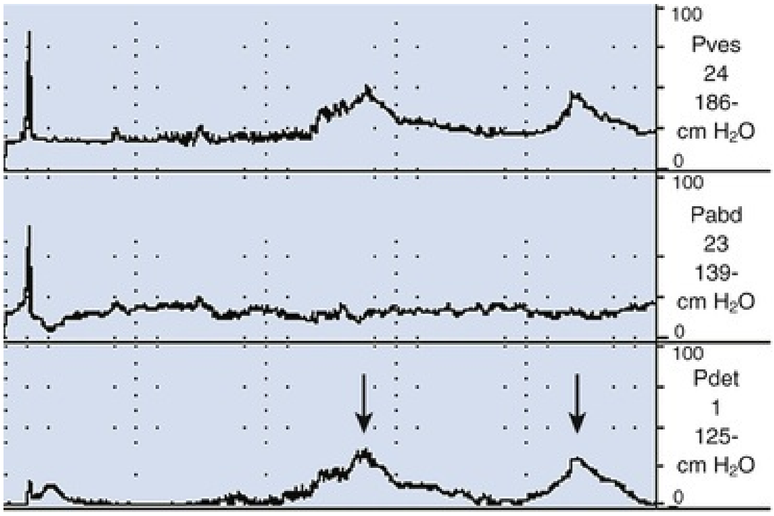

FIG. 114.4 Detrusor overactivity. In this tracing, there are two IDCs *(arrows).* There is a rise in Pves with no associated rise in Pabd, and therefore the subtracted Pdet looks identical to the Pves.

The presence of DO during UDS must be interpreted in the context of the patient's symptoms and condition. Ideally, a patient's symptoms should be reproduced during UDS, so we would expect DO to be accompanied by urgency or urgency incontinence, although it can occur and be significant without being symptomatic, particularly in neurogenic DO. However, **DO can also be “test induced” or clinically insignificant.** It has been reported in 14% to 18% of healthy asymptomatic volunteers undergoing UDS (Wyndaele and De Wachter, 2002; Robertson, 1999; van Waalwijk van Doorn et al., 1992). This is even more dramatic in ambulatory UDS in which the presence of DO has been found in as many as 69% of asymptomatic females (van Waalwijk van Doorn et al., 1996). Conversely, **failure to demonstrate DO on UDS does not rule out its existence.** It is well known that up to 50% of women with urgency incontinence do not demonstrate DO on UDS. **However, the ability to suppress DO during UDS may in and of itself be significant.** For example, Osman showed that patients with mixed incontinence and a normal CMG (no DO) not only had excellent cure rates for stress incontinence, but also had an 87% cure rate for urgency incontinence compared with only a 43% cure rate for urgency incontinence for women randomized to receive antimuscarinic medication instead of stress incontinence surgery (Osman, 2003).

It is important that the person performing the UDS be certain that the contraction is involuntary and not a voluntary attempt at voiding. Sometimes a patient may become confused during the study and actually void as soon as he or she feels the desire. The volume at which contractions occur and the pressure of the contractions should be recorded. It is often worthwhile to repeat the CMG at a slower filling rate if the patient experiences uncharacteristic symptoms associated with DO. If the patient experiences incontinence during an involuntary contraction (DO incontinence), this should be noted.

In addition to the presence of DO, its characteristics can be noted. DO can be observed as a single event or as multiple IDCs. It can be phasic (continuous), sporadic, or terminal (occurring at the end of filling near capacity). It can also be suppressed or nonabortable and may lead to leakage or precipitant micturition. Classifying DO in such a way can be valuable in certain circumstances. For example, overactive bladder symptoms associated with obstruction have been shown to have a higher likelihood of resolving with intervention (e.g., TURP) when DO occurs as a single terminal IDC rather than continuous or sporadic IDCs (Kageyama et al., 2000).

The detection of DO can be influenced by the patient's position. A review of studies on the influence of patient position found that 14 of 16 showed a higher incidence of DO in the vertical position (supine or standing) or onset of DO when changing to a vertical versus supine position (Al-Hayek et al., 2008). Thus, when the detection/documentation of DO is clinically important, it would seem appropriate to test the patient in the position in which he or she experiences specific symptoms.

Other parameters of the IDC have been suggested as factors that may contribute or predict upper urinary tract damage in cases of NDO (Musco et al., 2018). Maximal detrusor pressure is one of these values proposed to inversely relate to renal function; the higher the maximal detrusor pressure, the more impaired renal function (Shin et al., 2014; Cetinel et al., 2017). Further, the duration of the IDC has been reported as correlating with other signs of upper urinary tract deterioration (Musco et al., 2018). Here it is suggested the longer contraction in neurogenic patients, the more risk for upper urinary tract deterioration (Linsenmeyer et al., 1998; Elmelund et al., 2017).

In summary, DO is often a significant UDS observation and may explain a number of storage symptoms. In addition to its presence, the characteristics of DO should be noted. It is also important that clinicians recognize normal test-retest variation and that "usual lower urinary tract behavior" is not always replicated in the test setting.

The vesicoelastic properties of the bladder, based on its composition of smooth muscle, collagen, and elastin, normally produce a highly compliant structure. Therefore, as the bladder fills, there is little change in pressure (**see normalized CMG, Fig. 114.3**). **Compliance is the relationship between change in bladder volume and change in detrusor pressure** (Δ volume/Δ pressure) and is measured in mL/cm H_2O. The ICS recommends two standard points: the p_{det} at the start of bladder filling (usually zero) and the pdet at cystometric capacity or before the start of any detrusor contraction that results in significant leakage (Abrams et al., 2002). Both points are measured excluding any detrusor contractions**. It is difficult to definitively define what "normal compliance" is in terms of mL/cm H_2O.** Several authors have shown that mean values for compliance in healthy subjects range from 46 to 124 mL/cm H_2O (Hosker, 2004; Sorensen et al 1988; van Waalwijk van Doorn et al., 1992). However, there is great variation. For example, van Waalwijk van Doorn et al. showed a variation of compliance from 11 to 150 mL/cm H_2O (mean 46) in 17 healthy subjects (van Waalwijk van Doorn et al., 1992). Some of the variation in a "normal" bladder is likely because compliance per se is dependent on bladder capacity. Furthermore, various definitions of impaired compliance have been used (e.g., between 10 and 20 mL/cm H_2O), however, there is no consistent definition based on mL/cm H_2O. Stohrer et al. suggest that a value of less than 20 mL/cm H_2O is consistent with impaired compliance and implies a poorly accommodating bladder (Stohrer et al., 1999). However, examples can be cited (e.g., small cystometric capacity) in which this may not be the case. Therefore, **in practical terms, absolute pressure is probably more useful than a “compliance number” or value.** For example, it has been shown that storage greater than 40 cm H_2O are associated with harmful effects on the upper tracts (McGuire et al., 1981) (Fig. 114.5). Also, depending on the clinical scenario, a particular compliance in terms of mL/cm H_2O can mean very different things (Fig. 114.6). As a general rule, one might say that **prolonged storage at high pressures can lead to upper tract deterioration.** Elevated storage pressures and impaired compliance should be interpreted in the context of the clinical scenario. It has been shown that **conventional cystometry can provoke filling pressures higher than natural filling in some cases.** Robertson showed that for six patients with neuropathic bladder and severely impaired compliance on conventional cystometry, compliance was actually normal on ambulatory monitoring with natural filling (Robertson, 1999).

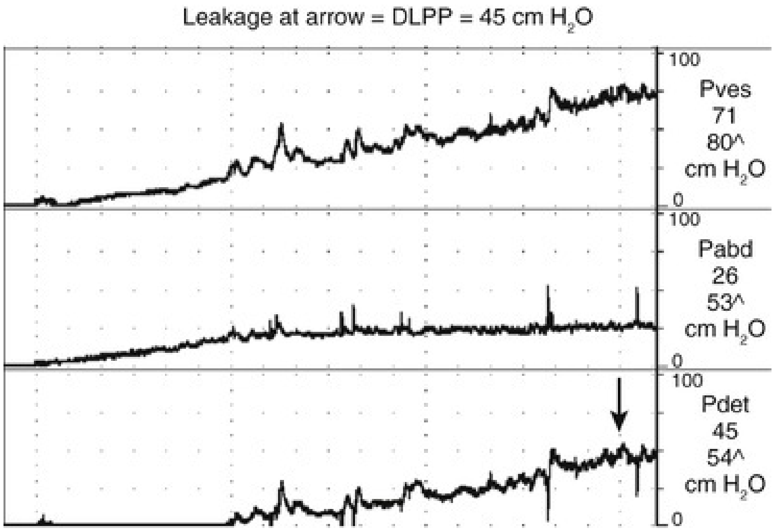

FIG. 114.5 Impaired compliance. Note the rise in pves (and pdet) with bladder filling. The pdet at the end of filling is approximately 45 cm H_2O, which is a potentially dangerous situation. In this case, the bladder was filled to a volume of 300 mL, so the compliance is 6.67 mL/cm H_2O. The *arrow* is the point at which incontinence was demonstrated, which is the

detrusor leak point pressure *(DLPP).*

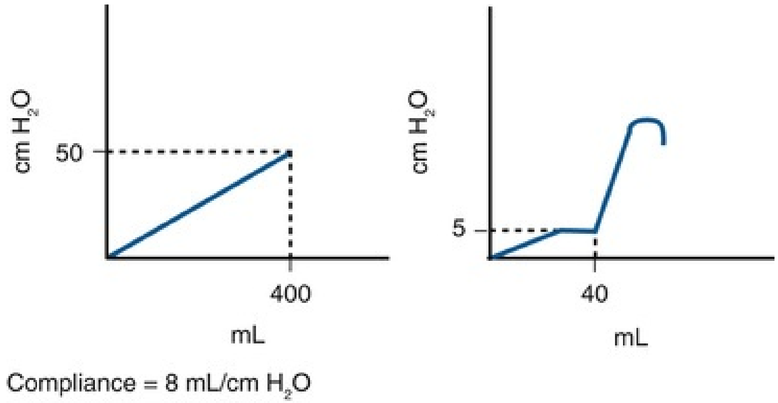

FIG. 114.6 A problem with measuring compliance. Two theoretical CMGs are shown. The one on the *left* demonstrates impaired compliance with a constant rise in pdet throughout filling. At 400 mL, the pdet is 50 cm H_2O (8 mL/cm H_2O), a dangerous situation. There is significant storage time when the det is >40 cm H_2O. The CMG on the *right* could represent a small-capacity bladder with DO and precipitant micturition. At a volume of only 40 mL, an IDC occurs. The pdet just before this was only 5 cm H_2O. The calculated compliance would be 6 mL/cm H_2O, the same as the one on the left. Yet the CMG on the right does not demonstrate a dangerous situation, just a highly symptomatic (incontinent) patient.

Impaired compliance is seen in a variety of neurologic conditions (spinal cord injury/lesion, spina bifida) and usually results from increased outlet resistance (e.g., detrusor–external sphincter dyssynergia [DESD]) or decentralization in the case of lower motor neuron lesions. It can also result from long-term BOO (e.g., benign prostatic obstruction) (Leng and McGuire, 2003) or structural changes such as radiation cystitis or tuberculosis. **Impaired compliance with prolonged elevated storage pressures is a urodynamic risk factor and usually needs to be treated to prevent renal damage (see Table 114.1).**

A number of factors can affect the measurement of compliance. Sometimes an increase in p_{det} during cystometry is seen as a result of rapid filling (filling during cystometry is almost always faster than physiologic filling). This is more of an accommodation problem rather than a true decrease in compliance. When p_{det} is seen to be rising, filling may need to be stopped or reduced to see if the effect is real. An IDC, particularly of a sustained and low amplitude, can be confused with impaired compliance. If filling is stopped and the pressure returns to baseline, then the compliance is not impaired. Finally, there are a number of "pop-off" mechanisms that can make compliance seem better than it actually is. Vesicoureteral reflux (VUR) and bladder diverticulum are two examples. With VUR, pressure is actually transferred to the refluxing renal unit and may be harmful. The volume that is refluxed into the upper tract can be a large volume (e.g., larger than bladder volume). Videourodynamics (see later) is very useful in these cases. Because a bladder diverticulum is actually part of the bladder, it may provide a protective effect for the upper tracts. Finally, an incompetent outlet may be a pop-off mechanism. This may only become apparent when outlet resistance is increased. This can be done during cystometry by occluding the outlet, but it may not be seen until the outlet resistance is surgically increased (e.g., with an artificial urinary sphincter or sling procedure).

Leak Point Pressures

The leak point pressure (LPP) is the pressure (spontaneous or provoked) that has caused fluid to be expelled from the bladder at the moment that it is visible outside the urethra (may also be used for extraurethral urine loss or stoma) (Rosier et al., 2017b). This term is inclusive of abdominal, cough or Valsalva, or detrusor LPP. When describing the LPP, provocation and the pressure recording site (e.g., the type of LPP) should be recorded.

From a practical standpoint, the LPP should be thought of as two distinct types: abdominal leak point pressure (ALPP) and detrusor leak point pressure (DLPP). The two are independent of each other and conceptually measure completely different things. Remember, they only occur in patients that have incontinence.

ALPP is a measure of sphincteric "strength" or, more practically, the ability of the sphincter to resist changes in abdominal pressure (McGuire et al., 1993)**. ALPP is defined as the intravesical pressure at which urine leakage occurs as a result of increased abdominal pressure in the absence of a detrusor contraction** (Abrams et al., 2002)**. This measure of intrinsic urethral function is applicable to patients with stress incontinence. An ALPP can only be demonstrated in a patient with SUI. Conceptually, the lower the ALPP, the "weaker" or less resistant the sphincter. There is no normal ALPP as patients without stress incontinence will not leak at any physiologic abdominal pressure. ALPP should be measured as the total abdominal pressure required to cause leakage, not the change in pressure**

(McGuire et al., 1993). Therefore, if ALPP is measured in the standing position, it should include the baseline p_{abd} (or p_{ves}), which is usually about 20 to 40 cm H_2O. Classically the reading is taken from the p_{ves} channel as long as there is no involuntary contraction (Fig. 114.7). In cases in which patients do not leak with a urethral catheter in place, the ALPP can be measured from the abdominal pressure channel either rectally or vaginally (Stohrer et al., 1999). The original description of ALPP was done at an arbitrary bladder volume of 150 mL; however, in some cases it is necessary to fill the bladder more. The volume at which ALPP is determined should be noted, as some investigators have found that it decreases at higher volumes (Faerber and Vashi, 1998). As a general rule, we start testing at 150 mL and then every 50 mL thereafter until SUI is demonstrated. If there is no SUI demonstrated at capacity, the urethral catheter is removed and ALPP is measured via the abdominal (usually rectal) catheter (provided there is no increase in p_{det} from DO or impaired compliance).

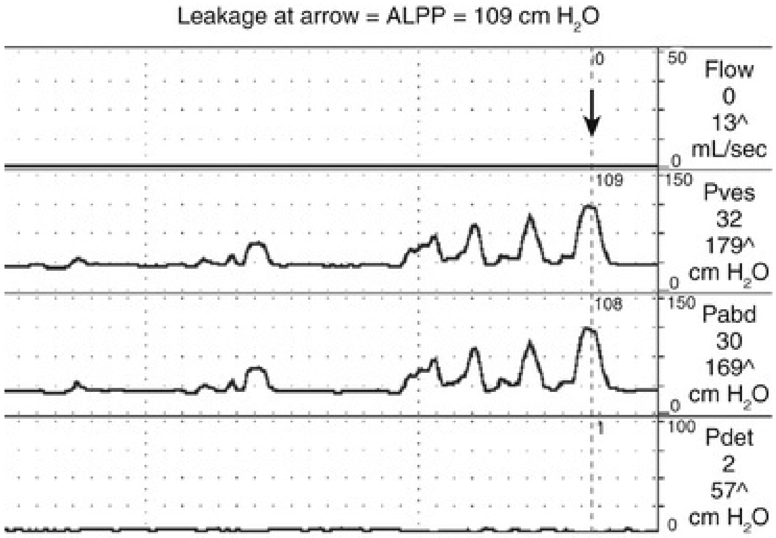

FIG. 114.7 Abdominal leak point pressure measurement. After progressive Valsalva maneuvers, leakage is demonstrated on the last one at 109 cm H_2O *(arrow).* There is no rise in Pdet.

Attempts have been made to quantify intrinsic sphincter deficiency (ISD) in women using ALPP. In 1993, McGuire et al. (1993) measured ALPP in 125 women with SUI. When the ALPP was less than 60 cm H_2O, all patients had high-grade incontinence, with 81% having continuous leakage and 75% having a fixed urethra (no urethral hypermobility). When ALPP was between 61 and 89 cm H_2O, 80% had pronounced urethral hypermobility and moderate to high-grade incontinence. When ALPP was 90 cm H_2O or greater, patients had lesser grades of incontinence and minimal to gross urethral hypermobility. The inference is that:

ALPP less than 60 cm H_2O signifies ISD.
ALPP between 60 and 90 cm H_2O is equivocal (there is a component of ISD).
ALPP greater than 90 cm H_2O indicates little or no ISD.

Current technology does not permit a method to distinguish between ISD in the face of urethral hypermobility (usually defined by placing a Q-tip in the urethra and assessing deflection from baseline to be greater than 30 degrees) in women. Therefore, although these ALPP values are often used as reference points, **they should be interpreted with caution.** For example, **if there is no urethral hypermobility, SUI must be caused by ISD, regardless of the ALPP.** Furthermore, Fleischmann et al. (2003) found that urethral hypermobility was equally common in women with lower versus higher ALPP. ISD and urethral hypermobility may coexist, and they do not define discrete classes of patients with SUI. Thus, an isolated measure of ALPP without considering other factors such as cystometry and urethral mobility is of limited utility in predicting success for commonly performed female SUI procedures (Hosker et al., 2009; Rosier et al., 2013). The use of ALPP in the diagnosis and treatment of female SUI is discussed further later in this chapter.

The term *ALPP* has been used interchangeably with *"Valsalva" leak point pressure (VLPP);* however, this is not entirely correct. ALPP can be measured during UDS by a voluntary Valsalva maneuver (VLPP) or by a cough leak point pressure (CLPP). In the same person, **VLPP tends to be significantly lower than CLPP.** Therefore, exact terminology and methods should be used when describing ALPP. ALPP can also be influenced by the presence or the size of a urethral catheter (Bump et al., 1995; Huckabay et al., 2005; Türker et al., 2010). It has been shown in women with SUI that the larger the catheter, the lower the ALPP. ALPP can also be measured without a urethral catheter by assessing the abdominal pressure via a rectal (vaginal or stomal) catheter. It has been shown that 15% of women with SUI (Türker et al., 2010) and 35% of men with postprostatectomy SUI will demonstrate ALPP only with the urethral catheter removed (Huckabay et al., 2005). Cough and Valsalva LPP are two ways to increase intraabdominal pressure, but we now have new terminology that is even more inclusive. ***Urodynamic stress test*** **is a new term that is defined as any physical effort used to elevate abdominal pressure during cystometry with the aim of examining SUI** (Rosier et al., 2017b).

The second type of leak point pressure is the detrusor leak point pressure (DLPP), which is a measure of detrusor pressure in a patient with decreased (poor) bladder compliance. It is defined as the lowest detrusor pressure at which urine leakage occurs in the absence of either a detrusor contraction or increased abdominal pressure (Abrams et al., 2002) **(see Fig. 114.5).** The higher the urethral resistance, the higher the DLPP will be. One can imagine that in a poorly compliant bladder, if outlet resistance is low, incontinence will occur at a relatively low or "safe" pressure. However, if outlet resistance is high, the pressure in the bladder will continue to increase as the bladder fills. There is potentially less incontinence, but eventually the pressure is transmitted to the upper tracts (Fig. 114.8).

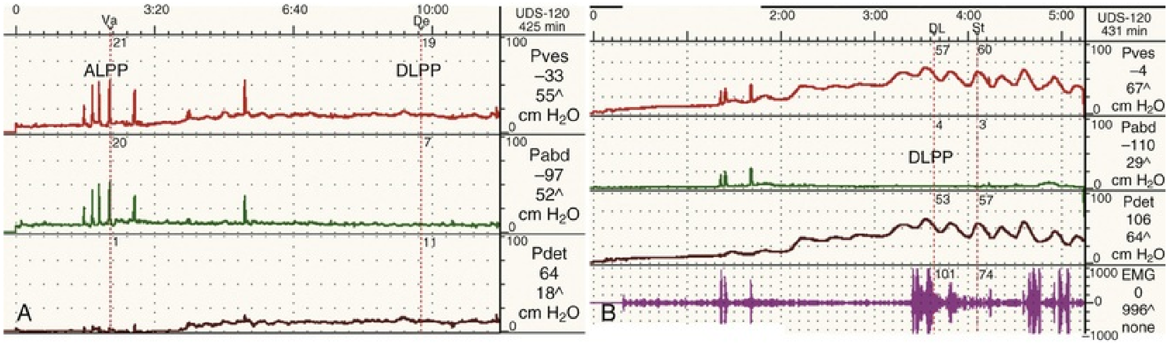

FIG. 114.8 Outlet resistance causes impaired compliance. UDS of two children with the same neurologic problem and symptoms but dramatically different findings. (A) UDS tracing of a young boy with spina bifida who is incontinent between catheterizations. The study shows a low-pressure system with poor outlet resistance and stress incontinence (ALPP demonstrated) and a low DLPP. His upper tracts are protected. (B) UDS tracing of a young girl with spina bifida who is incontinent between catheterizations. The study shows a high-pressure system with strong outlet resistance and a high DLPP. There was no stress incontinence. Her upper tracts are at risk. The difference in these two cases is the difference in storage pressures caused by the difference in outlet resistance.

From a clinical perspective, DLPP is important to assess in patients with upper motor neuron lesions with high storage pressures (usually secondary to DO and

DESD), patients with lower motor neuron disease causing “decentralization,” and in non-neurogenic patients with low bladder compliance (after multiple bladder surgeries, radiation, and tuberculous cystitis). The higher the DLPP, the more likely is upper tract damage as intravesical pressure is transferred to the kidneys. McGuire et al. (1981) documented the deleterious effects that a high detrusor leak point pressure has on the upper urinary tract; **a DLPP of greater than 40 cm H_2O resulted in hydronephrosis or vesicoureteral reflux in 85% of myelodysplastic patients. Although 40 cm H_2O clearly appears to be detrimental in the pediatric population that was studied, most experts would agree that there is limited evidence that an absolute cutoff of 40 cm H_20 should be used to determine a “safe” storage pressure. In reality, when treating impaired compliance, expert opinion leans toward the concept of aiming for as low a pressure that is “reasonably achievable”** (Rosier et al., 2013)**. This would be considerably below 40 cm H_2O in most cases.**

For example, more recent work in children with NLUTD (specifically myelodysplastic disease) suggests that a cut point for a DLPP of 20 cm H_2O had a higher sensitivity for upper urinary tract damage (91.5%) than the higher cut point of 40 cm H_2O (Tarcan et al., 2017). The original data regarding the high DLPP predicting upper tract deterioration were from retrospective cohort studies considered to be a low level of evidence. With more data and experience with this measure, the ICS published a teaching module in 2017 stating “that existing data confirm that patients with lower DLPP do better than patients with higher DLPP in terms of their upper urinary tract” (Tarcan et al., 2017). The idea of no reliable “safe/no safe” cutoff for DLPP is also echoed in a well-done systematic review of the value of urodynamic findings in predicting upper urinary tract damage in neurologic patients by concluding that a risk factor or upper tract deterioration is associated with simply “high detrusor leak point pressure” (not specifying a cutoff) (Musco et al., 2018). These papers acknowledged that there are urodynamic factors other than DLPP that influence upper urinary tract deterioration, such as compliance.

The significance of an elevated DLPP is that that bladder pressures are getting too high before the “pop-off” mechanism of urethral leakage occurs. In most cases, treatment is aimed at lowering bladder pressures so the DLPP is never reached. In some cases, DLPP can be lowered by decreasing outlet resistance, for example with a sphincterotomy in a patient with DESD. In these cases, follow-up UDS are useful to confirm the intended effect.

In summary, ALPP and DLPP—although both called “leak point pressure”—are completely different. The ALPP measures the sphincter response to increased abdominal pressure. The lower the ALPP, the “weaker” or less resistant the sphincter. The DLPP measures the injured bladder response to increased outlet resistance. The higher the resistance (e.g., DESD), the higher the DLPP, which is potentially dangerous to the upper tracts.

The ICS 2017 terminology for adult NLUTD also includes a new term for detrusor overactivity leak point pressure (Gajewski et al., 2017)**. As the name suggests, this is the lowest detrusor pressure rise with detrusor overactivity at which urine leakage first occurs. This is in the absence of voluntary detrusor contraction or increased abdominal pressure. The clinical significance of this will need to be further explored.**

Stress-Induced Detrusor Overactivity

Sometimes detrusor overactivity can be triggered by a rise in abdominal pressure (Fig. 114.9). Thus, the symptom may appear to be stress incontinence, but the condition causing the symptom is actually an involuntary contraction, not sphincteric weakness. In a patient with stress-induced detrusor overactivity (SIDO), it is important to note if there is also urodynamic SUI and/or DO independent of the SIDO. Similarly, the ICS (2017) has included in the term *cough-associated detrusor overactivity.* This describes DO (with or without leakage) occurring immediately after the cough pressure peak.

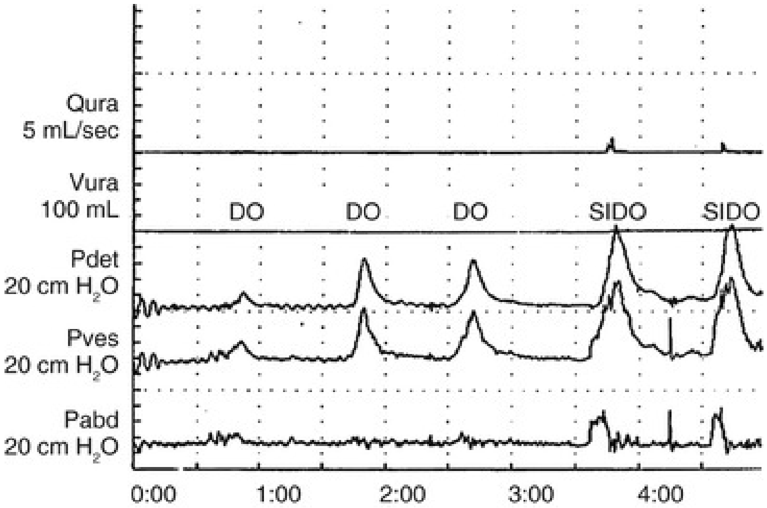

FIG. 114.9 Stress-induced detrusor overactivity. In this case, there are three episodes of detrusor overactivity *(DO)* preceding two episodes of

stress-induced detrusor overactivity *(SIDO).* In the case of SIDO, note that as Pabd increases so does Pves. Shortly after this, Pdet rises and continues long after Pabd returns to baseline. With both episodes of stress-induced overactivity, incontinence occurred as can be seen on the flow (Qura) curve. (From Nitti VW. Cystometry and abdominal pressure monitoring. In Nitti VW, ed. *Practical urodynamics*. Philadelphia, PA: WB Saunders; 1998:38–51.)

Occult Stress Incontinence

Stress incontinence on prolapse reduction, also referred to as *occult incontinence* or *latent stress incontinence*, is stress incontinence that is demonstrated in a clinically continent woman with pelvic prolapse only when the prolapse is reduced (Ballert et al., 2009; Haylen et al., 2010). Prolapse reduction can be done with a pessary, a packing, forceps, or manually. Technically, if this is demonstrated during urodynamic testing, it may be referred to as *urodynamic occult SUI.*

Urethral Pressure Profilometry

The method of urethral pressure profilometry (UPP) was popularized by Brown and Wickham in 1969 using small catheters with lateral apertures through which fluid is continuously infused (Brown and Wickham, 1969). Simultaneous bladder and urethral pressure is measured as the catheter is slowly withdrawn along the course of the urethra. The urethral pressure transducer measures the fluid pressure required to lift the urethral wall off the catheter side holes and thus elevates the circumferential and radial stresses induced by the presence of the catheter in the urethra and the slow urethral profusion. **Thus, urethral pressure is defined as the fluid pressure needed to just open a closed urethra** (Abrams et al., 2002). Accurate measurements are recorded only in those cases in which the urethra is distensible and therefore able to create a perfect seal.

Despite abundant literature on urethral profilometry, **its clinical relevance is controversial.** Many urologists do not routinely perform urethral profilometry. The urethral pressure profile (UPP) represents the intraluminal pressure along the length of the urethra in graphic form (Fig. 114.10). Several parameters can be obtained from the UPP:

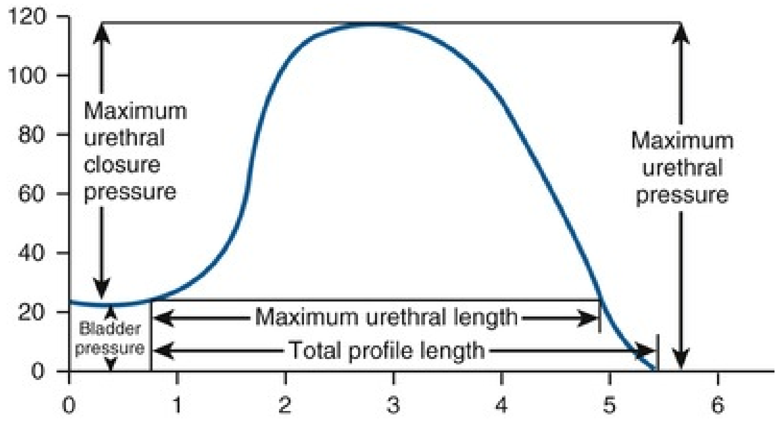

FIG. 114.10 Urethral pressure profile with appropriate parameters identified.

The urethral closure pressure (UCP) profile is obtained by subtracting intravesical pressure from urethral pressure.

Maximum urethral pressure (MUP) is the highest pressure measured along the UPP.

Maximum urethral closure pressure (MUCP) is the maximum difference between the urethral pressure and the intravesical pressure.

Functional profile length is the length of the urethra along which the urethral pressure exceeds intravesical pressure in women.

In most continent women, the functional urethral length is approximately 3 cm and the MUCP is 40 to 60 cm H_2O, but normal values vary widely. MUCP has also been used to define ISD. McGuire (1981) performed a retrospective evaluation of women who failed SUI surgery and found that a preoperative MUCP less than or equal to 20 cm H_2O resulted in higher surgical failure rates. These patients represented a specific subtype of SUI caused by a fixed, open urethra (type III SUI). In 1992, the term was redefined as ISD. **Many authors have used the definition of MUCP less than or equal to 20 cm H_2O to define ISD; however, this definition has many of the same problems as ISD definitions for ALPP.** Another caveat of UPP is that its measurement does not diagnose stress incontinence, and SUI is not required to measure it (contrary to ALPP). MUCP in incontinent women has been shown to be lower than in continent women, but there is certainly overlap (Schick et al., 2004). In addition, **MUCP is not always indicative of the severity of incontinence.** For example, there is a difference between the urethra of an incontinent patient whose MUCP

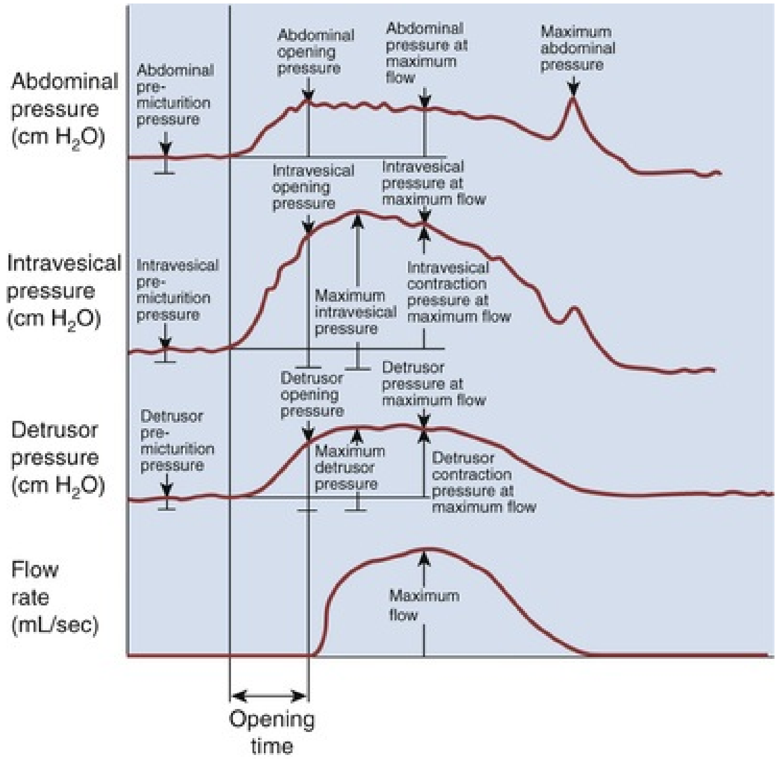
= 38 cm H_2O and that of a continent woman with the same MUCP.

In 2002, the ICS standardization subcommittee concluded that the clinical utility of urethral pressure measurement is unclear (Lose et al., 2002)**. Furthermore, there are no urethral pressure measurements that discriminate urethral incompetence from other disorders; provide a measure of the severity of the condition; or provide a reliable indicator to surgical success, and return to normal after surgical intervention** (Lose et al., 2002)**. In 2013, Rosier et al. reported that since the 2002 ICS report there is no new evidence, nor evidence regarding newer techniques, that intrinsic urethral pressure measuring quality has improved to a clinically relevant level with regard to sensitivity, specificity, and reliability. This recommendation was not altered in the 2017 edition (Rosier et al., 2017a).**

Voiding and Emptying Phase

Normal Voiding and Emptying

Evaluation of the voiding phase provides an assessment of both detrusor contractility and bladder outlet resistance. The bladder needs to contract and overcome the outlet resistance to allow for bladder emptying. In simple terms, abnormalities of bladder emptying are caused by “overactivity” of the bladder outlet (too much outlet resistance), “underactivity” of the detrusor (weak detrusor contraction force, short detrusor contraction duration, impaired contraction velocity), or a combination of both. The simultaneous measurement of detrusor pressure and urinary flow rate during voluntary voiding, known as a *pressure-flow study,* is the most accurate way to access these two critical parameters (Fig. 114.11).

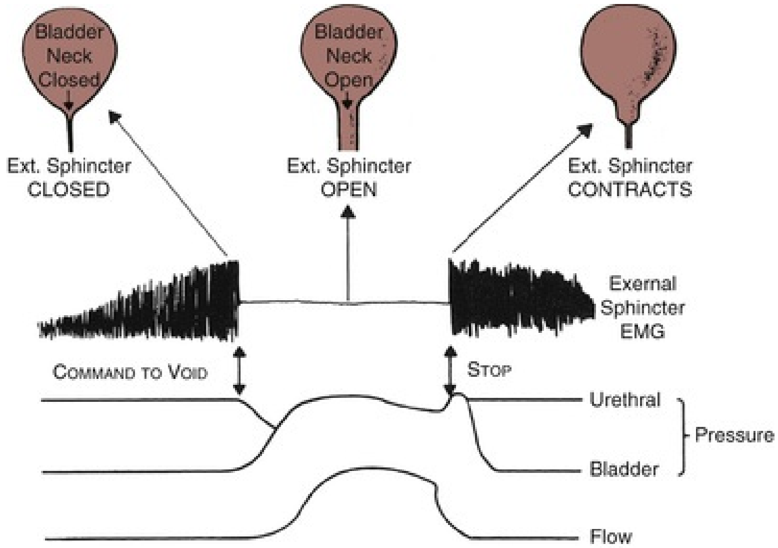


Abdominal pressure (cm H_2O)
Abdominal pre-micturition pressure
Abdominal opening pressure
Abdominal pressure at maximum flow
Maximum abdominal pressure
Intravesical pressure (cm H_2O)
Intravesical pre-micturition pressure
Intravesical opening pressure
Intravesical pressure at maximum flow
Maximum intravesical pressure
Intravesical contraction pressure at maximum flow
Detrusor pressure (cm H_2O)
Detrusor pre-micturition pressure
Detrusor opening pressure
Detrusor pressure at maximum flow
Maximum detrusor pressure
Detrusor contraction pressure at maximum flow
Flow rate (mL/sec)
Maximum flow
Opening time

FIG. 114.11 Schematic pressure-flow study labeled with recommended terminology.

When the void is "normal," the term *normal voiding function* can be used. This term indicates that flow rate and pressure-rise are within normal limits, begins more or less directly after permission to void, and ends with an empty bladder. When this does not occur during a urodynamic test, the term *bladder outflow obstruction* can be used; this is a cutoff of bladder outflow resistance based on the pressure-flow relation that is considered clinically relevant. It can be used in all patients regardless of age or gender (Rosier et al., 2017b).

To understand the relationship between bladder contractility and outlet resistance, one must start with an understanding of the normal micturition process. Normal voiding is accomplished by activation of the micturition reflex, which involves the following (Fig. 114.12):



Bladder Neck Closed
Bladder Neck Open
Ext. Sphincter CLOSED
Ext. Sphincter OPEN
Ext. Sphincter CONTRACTS
Exernal Sphincter EMG
COMMAND TO VOID
STOP
Urethral
Bladder
Pressure
Flow

FIG. 114.12 Physiology of micturition. See text for details. (From Blaivas JG. Pathophysiology of lower urinary tract dysfunction. *Urol Clin North Am* 12(2):215–224, 1985.)

- Relaxation of striated urethral sphincter
- Contraction of detrusor muscle
- Opening of vesical neck and urethra
- Onset of urine flow

This occurs as a result of coordination between pontine and sacral micturition centers with suprapontine input that allows for voluntary control of the micturition reflex.

UDS can evaluate the critical parameters during the voiding phase, which include detrusor contractility, relaxation of the bladder outlet, and coordination of sphincters (Fig. 114.13).

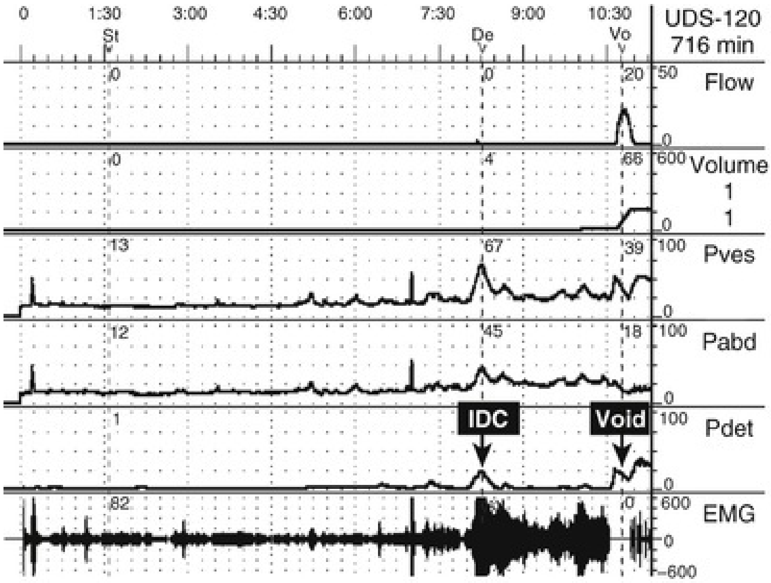


FIG. 114.13 Multichannel UDS showing filling and voiding phases with pressure and EMG readings. In this case, the patient experienced an IDC, which led to increased external sphincter contraction and an increase in EMG activity (guarding reflex). However, shortly after that, when the patient is given permission to void, there is quieting of the EMG (sphincter relaxation) followed by an increase in pdet and volitional voiding with a normal appearing uroflow curve.

According to the ICS, *normal detrusor function* is characterized by a voluntarily initiated continuous contraction that leads to complete bladder emptying within a normal time span and in the absence of obstruction. *Detrusor underactivity* occurs when there is a contraction of reduced strength and/or duration, resulting in prolonged bladder emptying and/or a failure to achieve complete bladder emptying within a normal time span. Finally, an *acontractile detrusor* occurs when there is no demonstrable contraction during UDS (Abrams et al., 2002). The term *areflexia* has been used in case of a neurologic cause of an *acontractile detrusor,* but it is now suggested that this term be replaced by ***neurogenic acontractile detrusor,* when appropriate** (Gajewski et al., 2017; Haylen et al., 2010).

The current definition of *detrusor underactivity* is hampered by the subjective interpretation of what constitutes reduced strength, reduced length of contraction, or prolonged emptying (Osman et al., 2014). Normal detrusor function and detrusor underactivity are somewhat “nebulously defined” in terms of absolute pressure because bladder pressure is influenced by outlet resistance. When evaluating detrusor function urodynamically, UDS must be correlated with clinical findings. For example, if a patient who normally voids is unable to void during a UDS, one cannot make a definitive diagnosis of “acontractile detrusor.” **If in the opinion of the person performing the test, in communication with the patient, the attempted voiding has not been representative, the term *situational inability to void as usual* can be used** (Rosier et al., 2017b). Specific measures of detrusor contractility are mentioned later in the text.

Urinary flow rate in combination with PVR is a useful clinical tool to assess emptying. When flow rate is reduced or PVR is elevated, it tells us that emptying is not complete, but it does not tell us why (e.g., obstruction vs. impaired contractility). Flow rate is also dependent on voided volume as there is a linear relationship between Q_{max} and voided volume, with a voided volume above and a hyperbolic relationship below a voided volume of 150 mL (Drach et al., 1979). Therefore, many authors have recommended a minimum voided volume of 150 mL to accurately assess uroflow. However, establishing a minimum voided volume puts major limitations on uroflowmetry as many patients with voiding dysfunction do not routinely void large enough volumes to be valuable. The corrected form of Q_{max} (Q_{max} divided by the square root of voided volume) may provide useful information in such patients (Boone and Kim, 1998). Over the years, several nomograms have been developed to define normal flow rates for a specified population and correct for voided volume. These include the Siroky nomogram for men (Siroky et al., 1979, 1980) and the Liverpool nomogram for men and women (Haylen et al., 1989).

The bethanechol supersensitivity test has been used to help distinguish the cause of detrusor underactivity as neurogenic or myogenic. It is based on Cannon's law of denervation, which states that denervated structures develop increased sensitivity to chemical stimulation. Lapides et al. applied this concept to the bladder (Lapides et al., 1962). The original bethanechol supersensitivity test described by these authors was performed by infusing liquid at a rate of 1 mL/sec to a volume of 100 mL, where the pressure is measured. This can be done up to three times and the pressure values averaged. The patient is then given 2.5 mg of bethanechol chloride (later revised to 0.035 mg/kg) subcutaneously, and the study is repeated at 10, 20, and 30 minutes. A normal bladder (or myogenically impaired bladder) should show an increase of less than 15 cm H_2O above the control value at 100 mL at 30 minutes. This is considered a negative study. A positive study, indicating a sensory or motor paralytic bladder, is a response of at least 15 cm H_2O above the control value. More recent studies have indicated that the bethanechol supersensitivity test is rather unreliable in predicting “neurogenic bladder.” Blaivas et al. (1980) reported only 76% sensitivity and 50% specificity. Even if the test were able to differentiate between neurogenic and myogenic dysfunction, treatment is often the same (e.g., clean intermittent catheterization). Bethanechol chloride, whether administered subcutaneously or orally, has not proven to be a consistently effective treatment for the underactive detrusor (Wein et al., 1978, 1980). In addition, a positive test does not predict improved voiding when it is used therapeutically**. Therefore, there is a very limited role for the use of the bethanechol supersensitivity test in clinical practice**.

Voiding Pressure-Flow Studies

Once the bladder is filled to cystometric capacity, the voiding portion of the pressure-flow study can begin. This examines the emptying phase of micturition. The same bladder and rectal (in some case vaginal or stomal) catheters are used while simultaneously collecting pressure data along with uroflowmetry. Ideally, such a study should assess a voluntary void. When there is flow of urine during an involuntary detrusor contraction, patients may contract the pelvic floor to prevent leakage. Such an event should be annotated on study. In addition, some subjects may have a difficult time voiding on demand in a public setting and with invasive monitoring in place. These stressors and the artificial environment of the testing need to be accounted for when interpreting the test.

As mentioned earlier, detrusor pressure during voiding is a function of outlet resistance. For a normal detrusor, the greater the outlet resistance is, the higher the detrusor pressure during voiding will be. This is accompanied by a reduced flow rate. A healthy bladder is able to overcome obstruction by contracting more forcefully, and, although flow may be slower, the bladder is able to empty itself. Over time, the detrusor may decompensate and may no longer be able to generate the necessary pressure to overcome obstruction. When this occurs, the result will be incomplete bladder emptying or retention of urine.

The voiding pressure-flow study helps assess two critical parameters related to the bladder and bladder outlet: detrusor activity (normal vs. impaired) and outlet resistance (obstructed vs. unobstructed). In general, the pressure-flow study can identify three fundamental conditions:

- Low (or normal) detrusor pressure and high (or normal) flow rate (normal, unobstructed voiding)

- High detrusor pressure and low (or normal) flow rate (obstruction)
- Low detrusor pressure with low flow rate (detrusor underactivity)

It is important to remember that these three categories are broad and general, and a final diagnosis should be made after considering UDS findings and the patient's clinical presentation (see later). It is also important to note that in cases of detrusor underactivity (i.e., low detrusor pressure and low flow), obstruction may coexist with detrusor underactivity, but making the “urodynamic diagnosis” of obstruction may not be possible if the detrusor is too decompensated.

The urodynamic manifestation BOO is high-pressure and low-flow voiding (or more practically speaking, increased pressure and reduced flow). Over time, if bladder decompensation results, detrusor underactivity or impaired contractility can result.

To use the common measures of obstruction and impaired contractility that are used today, it is important to understand basic bladder output and urethral resistance relations. Attempts to mathematically define urethral resistance date back to 1962 (Gleeson and Lattimer, 1962). Early equations calculating urethral resistance followed standard hydrodynamic formulae calculating outlet resistance. These concepts failed to consider that the urethra is not a rigid tube but rather has an active and distensible nature. They also failed to consider the importance of bladder volume. Rigid tube hydrodynamics were abandoned in favor of more dynamic ways to analyze micturition. In 1972, Griffiths introduced **bladder output relation (BOR),** which depicts the interrelations between bladder pressure and uroflow at a given volume and essentially measures the function of the bladder independent of the function of the urethra (Castro and Griffiths, 1972). Griffiths further defined a method to evaluate urethral resistance independent of bladder function, the **urethral resistance relation (URR).** According to this relation, as bladder pressure rises, the flow rate will be zero until the intrinsic bladder pressure equals the intrinsic urethral pressure. At this point, flow will start and the flow rate will rise rapidly with further increases in intrinsic bladder pressure. If pairs of simultaneously measured values of detrusor pressure and flow rate are plotted against each other throughout the course of a micturition event, a curve is obtained that shows the resistance to flow independent of detrusor function, representing the urethral resistance relation. If the urethra were relaxed or tightened during voiding, the

URR would move toward the left or right, respectively. Because the BOR represents the function of the bladder independent of the urethra and the URR depicts urethral function independent of bladder function, the actual detrusor pressure and flow rate are determined by the intersection of the bladder output relation and the urethral resistance relation, which is the point at which intrinsic bladder pressure equals urethral pressure (Fig. 114.14). A change in one of these relations during micturition would not affect the curve representing the other relation but would result in the point of intersection to moving along that curve.

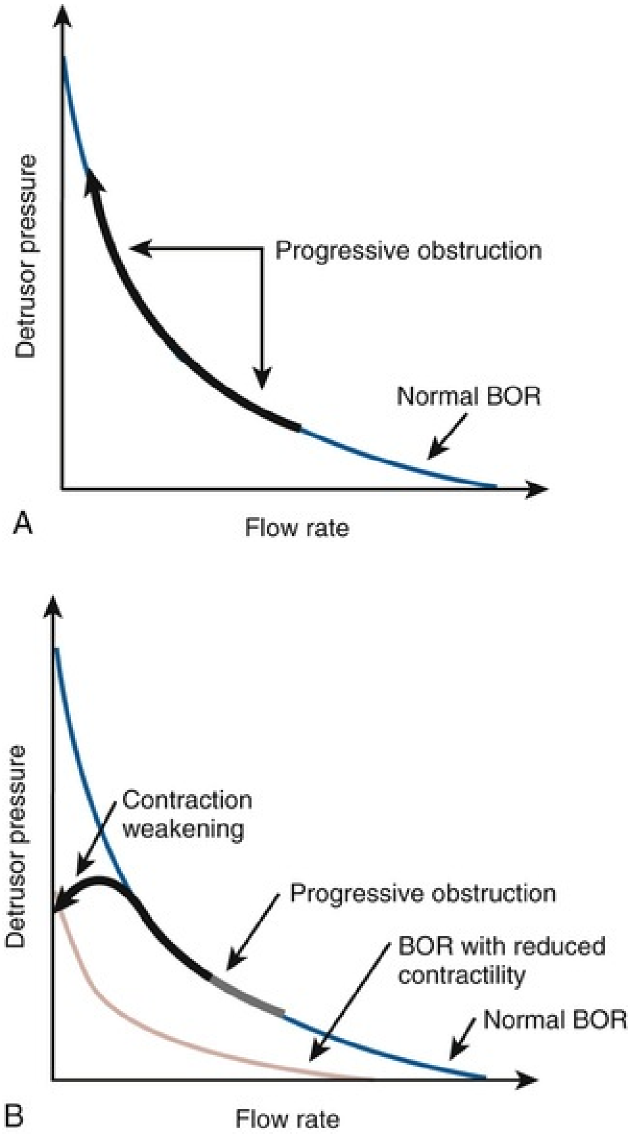

FIG. 114.14 (A and B) Relationship between detrusor pressure and flow in a given person—the bladder outlet relation. See text for details. (From Griffiths DJ. The mechanics of the urethra and of micturition. *Br J Urol*

45:497–507, 1973.)

In cases of suspected detrusor underactivity, a stop test can be performed. This is done by voluntary or mechanical interruption of urine flow during voiding (i.e., occluding the urethra). This allows for an estimation of isovolumetric detrusor pressure (P_{iso}) (Sullivan and Yalla, 2007). In a voluntary ‘ ‘stop test,’ ’ patients interrupt flow midstream by contracting the external urethral sphincter. In a mechanical “stop test,” interruption involves blocking the urethra by pulling a catheter balloon against the bladder neck during midstream or clamping or squeezing the urethra. In a continuous occlusion test, the outflow is occluded before the onset of detrusor contraction and the patient is asked to void against the occlusion. The three techniques show good correlation with each other in both men (Sullivan et al., 1995) and women (Tan et al., 2003). However, the voluntary stop test gives a lower P_{iso} than the other two (Sullivan et al., 1995).

Bladder Outlet Obstruction and Detrusor Underactivity in Men

The value of making a precise diagnosis of obstruction in men comes from the assumption that the outcomes of surgery to treat benign prostatic hyperplasia (BPH) and its consequent lower urinary tract symptoms (LUTS) are improved when obstruction can be documented. Because BPH and benign prostatic obstruction (BPO) are highly prevalent conditions, it was intuitive to use them as a model for defining obstruction. Most of the analytical work has focused on defining obstruction-based PFS. Three well known nomograms based on PFS have been described to diagnose men as obstructed, equivocal, or unobstructed. **These are the Abrams Griffiths nomogram** (Abrams and Griffiths, 1979)**; the Urethra Resistance Factor (URA)** (Griffiths et al., 1989)**; and the Linear Passive Urethral Resistance Relation or Schafer nomogram** (Schafer, 1990). The categories of obstruction described in these nomograms are based on observations of men who underwent surgery for LUTS (mainly transurethral resection of the prostate, TURP). After surgery, the detrusor pressure at maximum flow ($p_{det}Q_{max}$) was reduced in the obstructed group, reduced unpredictably in the equivocal group, and unchanged in the unobstructed group. Subsequently, Lim and Abrams (1995) showed that patients were similarly classified by all three methods. **They described a number, the AG number (now known as the bladder outlet obstruction index [BOOI]) derived from**

the equation for the slope of the line dividing obstructed from equivocal in the Abrams Griffiths nomogram, which is the same line dividing obstructed from slightly obstructed in the Schafer nomogram: BOOI = $p_{de}tQ_{max}$-2(Q_{max}). Subsequently Griffiths et al (1997) (**Fig. 114.15**) **described the ICS provisional nomogram which is now suggested for use for the diagnosis of obstruction in men with LUTS suggestive of BPH** (Abrams 1999)**. Men are considered obstructed if BOOI ≥40, unobstructed if BOO ≤20, and equivocal if BOOI is 20 to 40.**

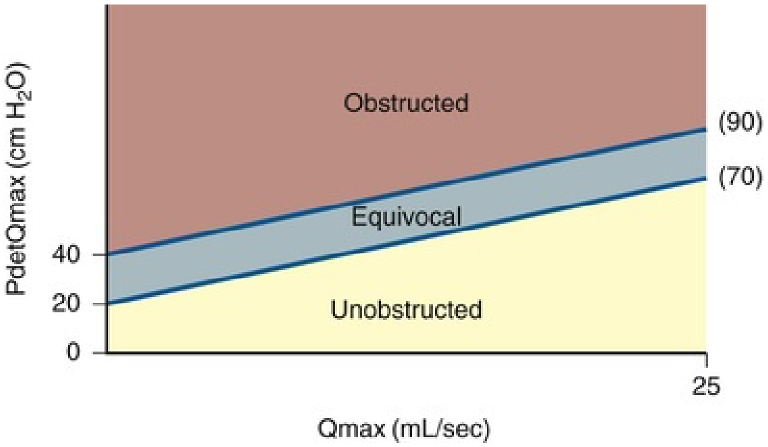

FIG. 114.15 The Provisional International Continence Society nomogram. See text for details.

Voiding pressure-flow studies show consistent reproducibility in the diagnosis of BOO in men. In a review of the topic Abrams et al. (2001) concluded that random variations of about 9 to 14 cm H_2O in pressure measurement and about 0.4 to 2 mL/s in maximum flow rate occur. In repeated studies during the same session, there was usually a systematic decrease of up to 4 cm H_2O in detrusor pressure and 0.4 mL/s in maximum flow rate. These variations have little clinical importance as they cause only 10% to 16% of patients to change classification on the ICS nomogram, and in all but about 1% the change is only by one class (e.g., from equivocal to unobstructed or from obstructed to equivocal).

Although much effort has focused on defining outlet resistance (i.e., obstruction), an index for bladder contractility can also be derived from the contractility groups Schafer (1995) described (strong, normal, weak, very weak). The **slope of Schafer's lines, now known as the bladder contractility index (BCI), is given by the formula: $p_{det}Q_{max}$ + 5(Q_{max})** (Abrams, 1999)**. Strong**

contractility is a BCI greater than 150; normal contractility is a BCI of 100 to 150; and weak contractility is a BCI less than 100 (Fig. 114.16). The BCI is the most common measure of bladder contractility used today because of its easy calculation and relationship to the BOOI and ICS nomogram.

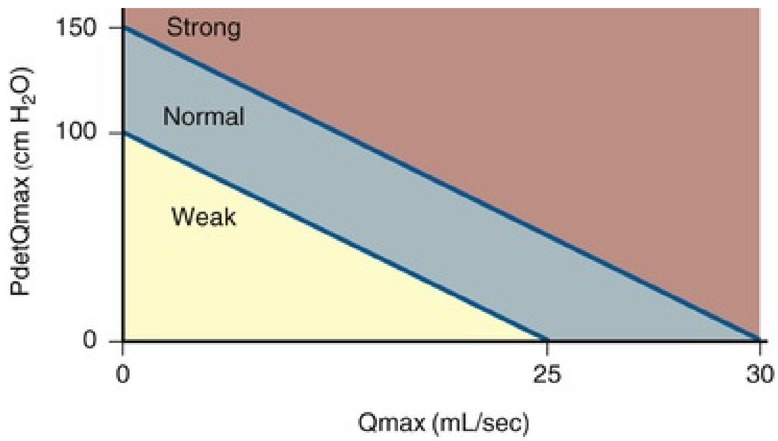

FIG. 114.16 The bladder contractility nomogram. See text for details.

Although contractility and obstruction can be independently measured, it is sometimes impossible to diagnosis obstruction in the face of detrusor underactivity using the ICS or other nomograms. For example, to make a diagnosis of unequivocal obstruction, BOOI must be at least 40 cm H_2O. That means that a p_{det} of at least 40 cm H_2O must be generated, and that assumes flow is zero. If the Q_{max} is 5 mL/s, then $p_{det}Q_{max}$ must be at least 50 cm H_2O. Thus, the ICS nomogram can exclude obstructed patients whose impaired contractility is the result of long-term obstruction. In such cases, clinical judgment becomes important.

Another measure of detrusor function is the Watts factor (WF), a quantification of detrusor power by a formula that estimates the power per unit area of bladder surface generated by the detrusor, corrected for the finite power required for either isometric contraction or for shortening against no load.

$$WF = [(P_{det} + a)(V_{det} + b) - ab]/2\pi$$

where V_{det} represents detrusor shortening velocity, and a and b are fixed constants (a = 25 cm H_2O; b = 6 mm/s), obtained from experimental and clinical studies (Griffiths, 1991).

Because detrusor pressure and velocity vary during the voiding phase, so too does the WF. Two points have been proposed as the most representative of detrusor contractility: the maximum WF (WF_{max}) (Griffiths et al., 1989) and the WF at maximum flow (W_{qmax}). An advantage of the WF calculation is that it depends minimally on bladder volume (Griffiths, 1991) and is not affected by the presence of BOO (Lecamwasam et al., 1998). However, it does not provide a measure of contraction sustainability and involves a complex calculation, limiting its use in clinical practice (Osman et al., 2014). In addition, threshold values for normal have not been validated; however, some have suggested using a W_{max} value of 7.0 W/m^2 (van Koeveringe et al., 2011).

BOO is associated with abnormalities of storage as well. This is presumably caused by changes in ultrastructure that occur with obstruction. Detrusor overactivity and impaired compliance occur in conjunction with obstruction. For example, about two-thirds of men with symptomatic BPO have DO that resolves 50% to 67% of the time with treatment of obstruction (Abrams et al., 1979). Reduced compliance is also associated with obstruction and has been shown to improve with treatment of obstruction (TURP) (Leng and McGuire, 2003).

An alternative to voiding pressure-flow studies as a way of measuring outlet resistance is the **micturitional urethral pressure profile (MUPP),** or voiding profilometry. This technique, popularized by Yalla, can both diagnose and localize obstruction (Yalla et al., 1980, 1981). The MUPP is performed with a triple-lumen catheter under fluoroscopic guidance similar to the static UPP described earlier. During voiding, the catheter is slowly withdrawn and the pressure is measured from the bladder neck through the anterior urethra (Steele et al., 1998). Normally during voiding, the pressure in the bladder is isobaric with the prostatic urethra and then pressure decreases across the membranous urethra and gradually decays along the rest of the anterior urethra. The membranous urethra is the narrowest segment of the bladder outlet during voiding, which accounts for the expected pressure drop of 20 to 30 cm H_2O. In patients with obstruction secondary to BPH, the MUPP is quite different. One will typically see a pressure disparity somewhere along the prostatic urethra. When this pressure disparity is greater than 5 cm H_2O, obstruction at the point of pressure drop is present. MUPP has been shown to be as effective in diagnosing BOO as standard PFS (DuBeau et al., 1995). An analysis of symptomatic BPH patients has shown that successful treatment outcomes have been achieved with treatment based on MUPP results (Lecamwasam et al., 1994).

In cases in which it is difficult to differentiate obstruction from detrusor underactivity by standard pressure-flow dynamics (e.g., in men with inefficient emptying in whom neither obstruction nor detrusor underactivity can be diagnosed by standard pressure-flow studies), P_{iso} can be measured by a stop test (see earlier). In men, a P_{iso} less than 50 cm H_2O is uncommon and has been considered to be diagnostic of detrusor underactivity (Comiter et al., 1996; Sullivan and Yalla, 1996).

Donkelaar et al. (2017) compared three methods to determine detrusor contraction strength in adult men including: LinPURR, BCI, and W_{max}. This retrospective comparison of more than 1200 UDS found all methods correlated well. The authors concluded that the LinPURR method was simple and intuitive. Further, this method had the advantage of combining detrusor contraction and bladder outflow obstruction simultaneously. WF_{max} calculation was suggested as a potentially used tool in studies aiming to improve detrusor contractility.

Currently urodynamic studies are “required” to diagnose detrusor underactivity, but there are no standardized criteria included in the ICS definitions for the “normal duration of detrusor contraction” and a “normal time span of micturition” (Abrams et al., 2002; Yang et al., 2018). This means there is no universal criteria to diagnose detrusor underactivity.

Bladder Outlet Obstruction in Women

BOO in women can present more of a diagnostic dilemma than in men. Because there is no highly prevalent condition (like BPH) that causes female obstruction, it is difficult to establish nomograms. Furthermore, nomograms derived for men cannot be applied to women as voiding dynamics differ. In addition, anatomic differences allow many women to empty their bladders by simply relaxing the pelvic floor, and some will augment voiding by abdominal straining. Minor elevations in detrusor pressure or decreases in flow rate, which might be considered insignificant in the male population, might signify BOO in women. Accordingly, clinicians must have a high index of suspicion based on the presence of lower urinary tract symptoms, incomplete emptying, persistent urinary tract infections, and a history of anti-incontinence surgery, prolapse, or other conditions.

In an effort to develop cutoff values for pressure and flow for the diagnosis of obstruction in women, Chassagne et al. studied a group of “clinically obstructed women” (after incontinence surgery; secondary to cystocele; or “other etiologies”) and compared them to a group of controls (women with stress incontinence) (Chassagne et al., 1998). Using receiver operator (ROC) curve analysis, they found the optimum sensitivity and specificity for predicting obstruction was obtained with a Q_{max} less than or equal to 15 mL/s and a $p_{det}Q_{max}$ of greater than or equal to 20 cm H_2O (74.3% sensitivity and 91.1% specificity). In 2000, with an expanded population, Lemack and Zimmern (2000) revised this to Q_{max} less than or equal to 11 mL/s and $p_{det}Q_{max}$ greater than or equal to 21 cm H_2O as optimal for the selection of patients with BOO. In the most recent publication, Defreitas et al. (2004) used normal asymptomatic women as the control group and found the highest sensitivity and specificity for predicting obstruction was obtained with Q_{max} less than or equal to 12 mL/s and $p_{det}Q_{max}$ greater than or equal to 25 cm H_2O. These cut-point studies have some limitations, namely obstruction was predefined clinically, and only patients with anatomic obstruction were included. Women with functional obstruction (e.g., from primary bladder neck obstruction or dysfunctional voiding) were not included in any of the cut-point analyses. This would be a difficult group of women to define “clinically” without any testing. Brucker et al. (2013) compared urodynamic findings of women with anatomic and functional outlet obstruction. Given the similarities in voiding pressure and large flow rate overlap, the authors suggest that future work attempting to characterize BOO in women need not exclude either group.

In 1999, Nitti et al. showed that the addition of fluoroscopic imaging to urodynamics was helpful in diagnosing female BOO (see Videourodynamics section later in this chapter). In this study, patients were classified as obstructed if there was radiographic evidence of obstruction between the bladder neck and distal urethra in the presence of a sustained detrusor contraction of any magnitude. In addition to diagnosing BOO, it also localizes the site of obstruction and allows for the diagnosis of obstruction in the face of impaired contractility if indeed the site can be localized. **With both the videourodynamic and cut-point criteria, there is a significant difference in mean Q_{max} and $p_{det}Q_{max}$ in the group of obstructed women versus the group of unobstructed women, but there is a large overlap of values between obstructed and unobstructed patients. This demonstrates that absolute pressure and flow values are imprecise and that another parameter (e.g., radiographic or clinical evidence of obstruction) is necessary for diagnosis.**

Blaivas and Groutz (2000) presented a nomogram for defining female BOO. Citing the fact that in their series there was a significantly higher flow rate in the same woman without a catheter, they choose to use a noninvasive flow rate in their nomogram. Also, because they found no statistical difference between $p_{det}Q_{max}$ and $pdet_{max}$ in obstructed or unobstructed patients, they choose $pdet_{max}$ as the pressure parameter. Using cluster analysis to classify patients with low- and moderate-grade obstruction, they formulated the nomogram. The nomogram places women into four zones: no, mild, moderate, and severe obstruction. An obvious criticism of the nomogram is that it is based on two separate voids (invasive and noninvasive), and one must assume that the pressure characteristics of the void are the same. Akikwala et al. (2006) compared the three methods of diagnosing BOO in women and found good concordance between the videourodynamic and cut-point criteria. They also noted that the Blaivas-Groutz nomogram overdiagnosed obstruction compared with the other two methods.

Obstruction in women cannot be defined by the ICS nomogram or the BOOI, as these will grossly underestimate female BOO. This is because normally women void at much lower pressures than men, and therefore the obstructed female bladder outlet may not respond as dramatically (or at least with the same pressures) as in the male. There is no condition in women that causes BOO as commonly as BPO in men, and therefore creating a consistent standard is difficult. Thus, concepts are the same (higher pressure and lower flow), but the values are different and less well defined. Those who are interested are referred to suggested readings (Akikwala et al., 2006; Blaivas and Groutz, 2000; Defreitas et al., 2004; Nitti et al., 1999).

More recently, the Solomon-Greenwell nomogram was described to diagnose BOO in women (Solomon et al., 2017). The authors used radiographic obstruction (VUDS criteria) as the referent. Here a cohort of 185 women were plotted $P_{det}Q_{max}$ against Q_{max}, and cluster analysis was performed to determine an axis that best divided the definitely obstructed and unobstructed (functional and anatomical obstruction). The yielded an axis of $P_{det}Q_{max} = 2 \times Q_{max}$. Using an additional 350 women added to the cohort, they calculate a nomogram representing the probability of obstruction. **Presented as a mathematical formula, if $P_{det}Q_{max} - 2.2 \times Q_{max}$ is less than 0, there is a less than 10% chance of obstruction; if it is greater than 5, there is likely obstruction (50%); and if it is greater than 18, obstruction is almost certain (>90%).**

Theoretically, one can consider measuring P_{iso} via a stop test in women to measure detrusor strength and to help differentiate between detrusor underactivity and obstruction. P_{iso} has not been used to accurately characterize women. However, it is known that P_{iso} values are significantly lower in older women than in men. Tan et al. (2003) showed that the mean P_{iso} in women at least 53 years of age with urgency incontinence was 31.2, 47.2, and 48.7 cm H_2O for the voluntary, mechanical, and continuous stop test, respectively.

Detrusor underactivity as its own condition has also gained more interest recently in women, but like in men, there is still no agreed universal criteria. Yang et al. (2018) studied a large cohort of women with VUDS and found that those with detrusor underactivity (defined as women who did not have a voiding detrusor contraction of more than 10 cm H_2O and needed to void by abdominal straining, or were unable to void) had decreased bladder sensation compared with the normal group and other voiding dysfunctional groups. Further, they describe a negative association between detrusor contractility and bladder sensation in linear regression.

Sphincter Coordination

The External Sphincter

Normal voiding requires external sphincter relaxation followed by contraction of the detrusor. The external sphincter (and internal sphincter) should remain relaxed until voiding is complete. In normal voluntary voiding, a rise in detrusor pressure is preceded by a fall in urethral pressure and relaxation of the external sphincter as measured by electromyography (EMG). The sphincter and urethral pressure remain low during voiding and then increase when voiding is completed **(Fig. 114.17). Failure of the sphincter to relax or stay completely relaxed during micturition is abnormal** (Abrams et al., 2002)**. Thus, normally EMG activity decreases before a voluntary bladder contraction; however, it is not abnormal for EMG activity to increase with an involuntary contraction as part of a guarding reflex to inhibit the IDC (see Fig. 114.13).**

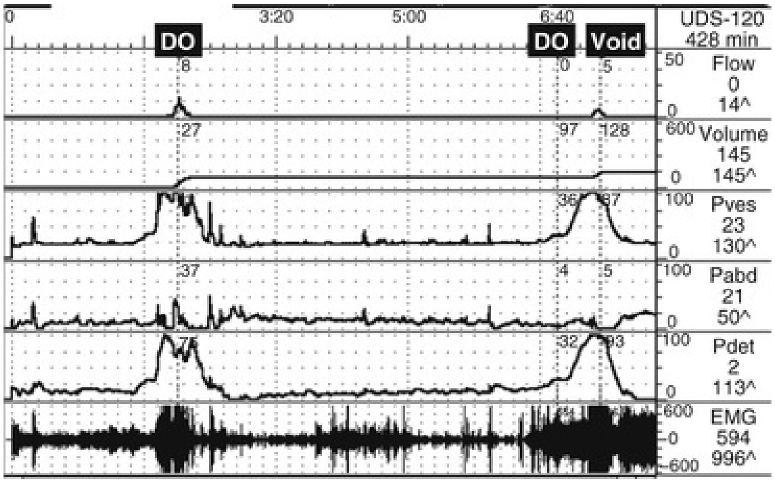

FIG. 114.17 UDS tracing of a patient with myelodysplasia and neurogenic DO and DESD. Note the initial IDC associated with DESD and incontinence (measured on the flow channel). With refilling, there is again DO with DESD. Then the patient is told to voluntarily void, and there is persistent increased EMG activity. As a result, there is high-pressure, low-flow voiding (obstruction from the dyssynergic sphincter).

There are several abnormalities related to external sphincter relaxation (or lack thereof). **DESD occurs when there is an involuntary increase in external sphincter activity associated with DO and also with voiding (see Fig. 114.18). It is caused by a neurologic lesion in the suprasacral spinal cord. DESD can produce profound changes as the detrusor involuntarily contracts against a relatively closed sphincter. This will result in high pressures and can even cause impaired bladder compliance over time. Because long periods of elevated detrusor pressure during bladder filling or (abnormally prolonged) voiding put the upper urinary tract at risk, DESD may be considered a urodynamic risk factor for upper tract deterioration (see Table 114.1)** (Kurzrock and Polse, 1998; McGuire et al., 1996; Tanaka et al., 1999)**. True DESD only occurs when there is a known neurologic lesion above the sacral micturition center. The higher the lesion, the more likely DESD will occur** (Blaivas, 1982)**. If there is no neurologic lesion, then the "dyssynergia" is considered to be a learned behavior and is known as *dysfunctional voiding*.** The term *dysfunctional* describes malfunction (failure to relax or involuntarily contraction of the external sphincter) during the voiding phase only and says nothing about the storage phase (Neveus et al., 2006). However, it is entirely possible and quite common for a patient to experience storage symptoms (and UDS abnormalities) associated with dysfunctional voiding. Although the condition has been extensively described in children, it has also been described in adult men (He et al., 2010; Kaplan et al., 1997; Nitti et al., 2001) and women (Carlson et al., 2001) and can be a major cause of LUTS. It is recommended that when dysfunctional voiding is diagnosed by UDS, the flow pattern (reduced and/or intermittent) is confirmed by noninvasive uroflowmetry to rule out a test-induced phenomenon (Barrett and Wein, 1981; Carlson et al., 2001). Other studies have suggested increase diagnostic accuracy of dysfunctional voiding using fluoroscopy at the same time as pressure-flow studies (Brucker et al., 2012). He et al. (2010) used the following diagnostic criteria in men: no abnormality detected in the history; no symptoms on examination for neurologic diseases; transient and intermittent closure of the external sphincter during voiding detected by EMG and fluoroscopic cystourethrography; and higher external sphincter EMG activity with no abdominal pressure increase in the voiding phase. Uroflowmetry was assessed individually to show any discontinuity in a diagram of urinary flow, in conditions with as little external interference as possible.

The urethral sphincter can also be described as “nonrelaxing,” resulting in reduced urine flow. The term *delayed relaxation of the urethral sphincter* is also used to described hindered relaxation during an attempt at voiding (resulting in delay of urine flow) during pressure-flow studies of adults with neurologic lower urinary tract dysfunction (Gajewski et al., 2017).

The Internal Sphincter

Just as there can be a lack of coordination of the detrusor and external sphincter, so too can there be dyscoordination of the internal sphincter or bladder neck. In the case of neurologic disease, if a suprasacral spinal cord lesion is above the level of the sympathetic ganglia (T10 to L1), detrusor–internal sphincter dyssynergia (DISD) may occur in conjunction with external sphincter dyssynergia (Pan et al., 2009). In non-neuropathic men, women, and children, the phenomenon of bladder neck dyssynergia or primary bladder neck obstruction is a well-known cause of LUTS, although its exact etiology is not known (Combs et al., 2005; Diokno et al., 1984; Norlen and Blaivas, 1986). Conditions of internal sphincter dysfunction require videourodynamics for an exact diagnosis and are described in the next section.

Key Points

- Normally detrusor pressure should remain near zero during the entire filling cycle until voluntary voiding is initiated.
- The ability to calculate subtracted p_{det} allows one to distinguish between a true rise in detrusor pressure (either via a contraction or loss of compliance) and the effect of increased abdominal pressure.
- It is important that the person performing the UDS be absolutely sure that a bladder contraction is indeed involuntary. Sometimes patients become confused during the study and actually void as soon as they feel the desire.
- “Usual lower urinary tract behavior” is not always replicated in the test setting.
- As a general rule, prolonged storage at high pressures can lead to upper tract deterioration.
- ALPP and DLPP, although both called “leak point pressure” are completely different. The ALPP measures the sphincter response to increased abdominal pressure. The lower the ALPP, the “weaker” the sphincter. The DLPP measures the injured bladder response to increased outlet resistance. The higher the resistance, the higher the DLPP, which is potentially dangerous to the upper tracts.
- According to the ICS, *normal detrusor function* is characterized by a voluntarily initiated continuous contraction that leads to complete bladder emptying within a normal time span and in the absence of obstruction.
- According to the ICS, *detrusor underactivity* is characterized by a contraction of reduced strength and/or duration resulting in prolonged bladder emptying and/or a failure to achieve complete bladder emptying within a normal time span.
- The urodynamic manifestation of BOO is high-pressure and low-flow voiding.
- Normally EMG activity decreases before a voluntary bladder contraction; however, it is not abnormal for EMG activity to increase with an involuntary contraction as part of a guarding reflex to inhibit the IDC.
- True DESD only occurs when there is a known neurologic lesion above the sacral micturition center.

Videourodynamics

Videourodynamics (VUDS) consists of the simultaneous measurement of UDS parameters and fluoroscopic imaging of the lower urinary tract. It provides the most precise evaluation of voiding function and dysfunction and is particularly useful when anatomic structure and function are important (Drake et al., 2016; Keane et al., 1993; McGuire et al., 1996). Examples of when VUDS are useful include the localization of obstruction, detecting incontinence not seen on physical examination, and evaluating vesicoureteral reflux during storage and/or voiding. It can be particularly useful in cases of NLUTD. VUDS is the only way to evaluate bladder neck function and/or dysfunction. The fluoroscopic images can also confirm sphincteric dysfunction when diagnosed by EMG or give a diagnosis if EMG is questionable (Brucker et al., 2012). Also, there are instances in which a known anatomic abnormality exists and simultaneous imaging can determine if that abnormality is playing a role in voiding dysfunction or urodynamic parameters (e.g., bladder or urethral diverticulum, vesicoureteral reflux).

VUDS can be performed using a variety of different methods. Most commonly fluoroscopy is employed using a C-arm. This gives the most flexibility in allowing patient positioning. However, a fixed unit with a fluoroscopy table that can move from 90 to 180 degrees may also be used. It is important that the patient be positioned properly to evaluate the desired function and anatomy. For example, SUI in men and women is best evaluated in the standing position. Voiding is best evaluated in the position that the patient characteristically voids (usually sitting for women and standing for men). It is always recommended that fluoroscopy time be limited and focus on situations of high yield such as during provocative maneuvers to demonstrate SUI, during rises in pressure associated with impaired compliance or involuntary contractions, and during voiding.

VUDS can be extremely useful for the diagnosis of BOO in women (Nitti et al., 1999; Blaivas and Groutz, 2000). In 1999, Nitti et al. described the VUDS criteria for the diagnosis of obstruction in which radiographic evidence of obstruction between the bladder neck and urethral meatus during voluntary voiding defines and localizes obstruction. **Primary bladder neck obstruction can only be diagnosed on VUDS.** Figs. 114.18 and 114.19 distinguish between the two most common causes of functional obstruction in women, primary bladder neck obstruction and dysfunctional voiding.

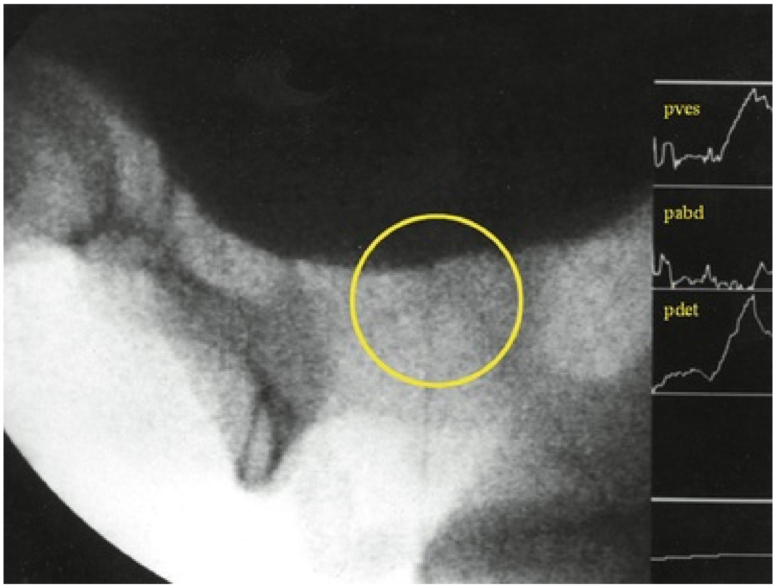

FIG. 114.18 Primary bladder neck obstruction in a 35-year-old woman with obstructive voiding symptoms and intermittent urinary retention. Note the failure of the bladder neck to open at all, despite a detrusor contraction of greater than 60 cm H_2O. (From Nitti VW. Primary bladder neck obstruction in men and women. *Rev Urol* 7[Suppl 8]:S12–S17, 2005.)

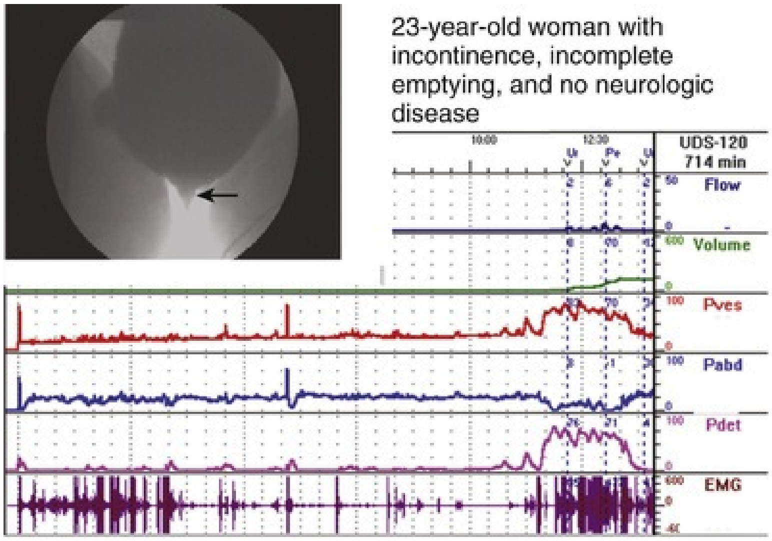

23-year-old woman with incontinence, incomplete emptying, and no neurologic disease

FIG. 114.19 Dysfunctional voiding. UDS of a 23-year-old woman with urgency incontinence, incomplete emptying, and no neurologic disease. Just before voiding, there is an IDC. With voiding, there is increased EMG activity. The fluoroscopic picture taken during voiding shows a

characteristic “spinning-top urethra” with the level of obstruction at the external sphincter. The high-pressure, low-flow voiding is also characteristic of obstruction.

Similarly, VUDS can be used to evaluate LUTS in young men and, in particular, make a diagnosis of primary bladder neck obstruction (Kaplan et al., 1996; Norlen and Blaivas, 1986). Although presence of obstruction can be diagnosed by pressure-flow studies alone, many surgeons do not feel comfortable performing surgical intervention on a young man without localizing the obstruction. In addition, sometimes bladder neck obstruction can present without classical findings of high pressure and low flow. Three distinct types have been described (Nitti et al., 2001): classic high-pressure–low-flow (type I); normal-pressure–low-flow with narrowing at the bladder neck (type II); and delayed opening of the bladder neck (type III). Fig. 114.20 shows types I and II male primary bladder neck obstruction. Fluoroscopy is critical to the diagnosis, especially in types II and III. In fact, simultaneous fluoroscopy during UDS can localize the anatomic site of obstruction in many conditions (e.g., BPO, bladder neck contracture, urethral stricture) once the “urodynamic diagnosis” of obstruction is confirmed.

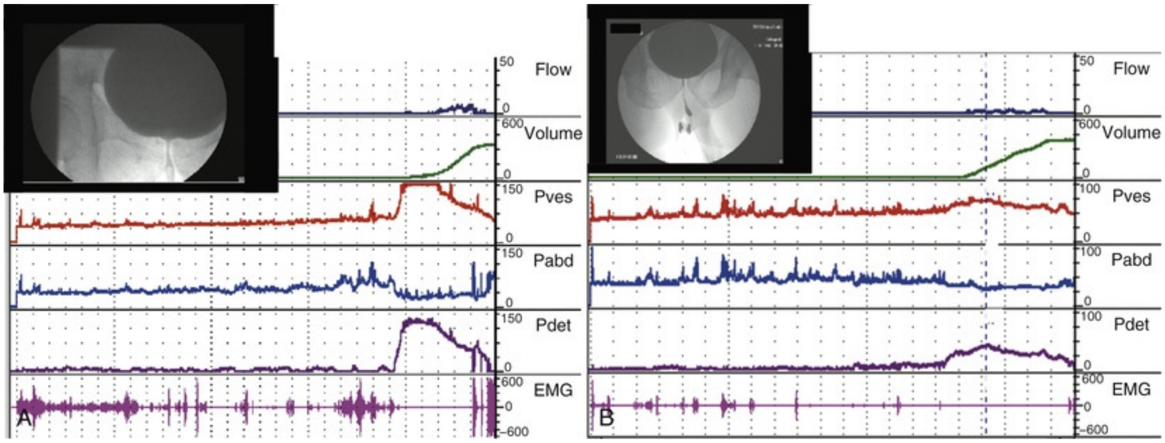

FIG. 114.20 Primary bladder neck obstruction (dysfunction). (A) Type 1—high-pressure, low-flow voiding in a 45-year-old male with severe LUTS including frequency, urgency, and decreased force of stream. Image is taken during voiding; note the incompletely opened bladder neck. (B) Type 2—normal-pressure low-flow voiding in a 35-year-old male with similar LUTS as in (A). There is also an incompletely open bladder neck during voiding. The much lower voiding pressures compared with (A) should still be enough to empty normally, though there may be a component of impaired contractility because the bladder was unable to compensate for the increased resistance at the bladder neck. (From Nitti VW. Primary

bladder neck obstruction in men and women. *Rev Urol* 7[Suppl 8]:S12–S17, 2005.)

VUDS has been shown to be very useful in diagnosing voiding phase dysfunction in women and can be more accurate than surface electrodes in determining EMG activity. We recently found that VUDS was more accurate than surface EMG in diagnosing dysfunctional voiding and differentiating it from primary bladder neck obstruction in women (Brucker et al., 2012). In this study, it was assumed that VUDS would be the most accurate method to diagnose voiding phase dysfunction in women. We found that that if the surface EMG findings alone were used, the incorrect diagnosis would have been made in 20.6% of the women with dysfunctional voiding diagnosed by VUDS. In contrast, increased EMG activity during voiding was seen in 14.3% of women with primary bladder neck obstruction by VUDS (e.g., a patient voiding with high pressure and low flow without any funneling or opening of the bladder neck and during voiding).

The AUA/SUFU Urodynamics Guideline supports the use of VUDS in young men and women without an obvious anatomic cause of obstruction as it can differentiate between functional causes of obstruction such as primary bladder neck obstruction and dysfunctional voiding (Winters et al., 2012). The guideline further states that VUDS is the only diagnostic tool that can document pressure-flow parameters and localize functional bladder neck obstruction. However, the panel recognized that studies have not been performed comparing treatment outcomes of men and women diagnosed with VUDS versus those who had treatment but no VUDS.

VUDS is an important aid in diagnosing NLUTD and other conditions that may cause elevated storage pressures. In cases in which vesicoureteral reflux occurs, the volume and pressure at which it starts should be documented. If possible, the side(s) and degree of reflux should also be noted. In cases of impaired compliance in which there is compensation by the “pop-off” mechanism of vesicoureteral reflux, the impaired compliance might not be identified unless the reflux is also recognized by fluoroscopy (Fig. 114.21). Without knowing there is reflux, the measured compliance may be underestimating the true bladder compliance, a potentially unsafe situation.

FIG. 114.21 (A) UDS of a 75-year-old male with elevated PVR and left hydronephrosis. The end filling pressure is 20 cm H_2O, indicating “safe” storage pressures. (B) VUDS shows early reflux at low bladder pressures and significant reflux as bladder filling continues. This represents a “pop-off” mechanism, and the true “functional” bladder compliance is actually significantly more impaired than would be determined by bladder pressure alone.

In addition, an accurate DLPP can be obtained in cases in which it would otherwise be impossible to position a patient to observe leakage (e.g., some tetraplegics). Furthermore, in cases of possible DISD (often found in conjunction with DESD), VUDS is the only way to make the diagnosis and can dramatically change treatment (Fig. 114.22). **The EAU guidelines state that VUDS is the gold standard for invasive UDS in patients with NLUTD** (Pannek et al., 2013)**. If VUDS is not available, then a filling CMG plus pressure-flow study should be done.** The AUA/SUFU Urodynamics Guidelines also recognize the value of VUDS in patients with neurogenic LUTD (Winters et al., 2012). The panel concluded that adding simultaneous fluoroscopy during CMG and pressure-flow study provided additional worthwhile diagnostic information beyond what either study alone could provide. However, they also warn that because radiation exposure is additive, studies should be done in a manner that provides the desired clinical information at the lowest possible radiation dose to the patient.

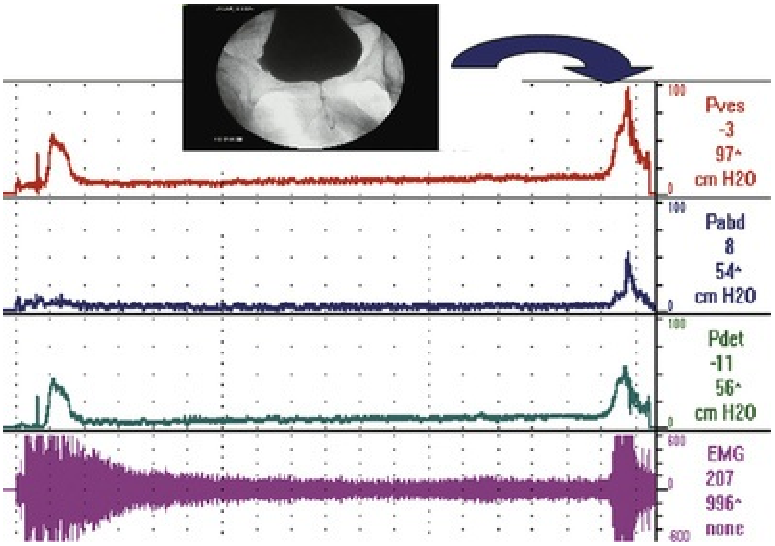

FIG. 114.22 Video-urodynamic evaluation of a cervical spine-injured man with neuropathic voiding dysfunction with incontinence and incomplete emptying. The UDS tracing clearly shows DO with DESD (increased EMG activity with involuntary contraction. However, it is only with the fluoroscopic view of the bladder outlet during an involuntary contraction that detrusor–internal sphincter dyssynergia is diagnosed (the bladder neck remains relatively closed).

VUDS may improve diagnostic acumen in some selected patient populations (Marks and Goldman, 2014), but it must be weighed against the added risk for radiation exposure (Brucker et al., 2016) and the potential increase in health care costs. VUDS may not be readily available to all heath care providers. **VUDS is the diagnostic tool of choice for documenting bladder neck dysfunction in men and women. In addition, patients at high risk for complicated voiding dysfunction, such as those with known or suspected NLUTD, unexplained urinary retention in women, prior radical pelvic surgery, urinary diversion, prerenal or postrenal transplant, or prior pelvic radiation, should be considered for referral to a center with VUDS capabilities if a complete and accurate diagnosis cannot otherwise be obtained** (Scarpero et al., 2009).

Key Point

- VUDS is usually considered the gold standard for invasive UDS in patients with NLUTD.

Ambulatory Urodynamics

Ambulatory urodynamic studies are defined as a functional test of the lower urinary tract, utilizing natural filling, and reproducing the subject's everyday activities (Abrams et al., 2002). The development of natural and slow-filling urodynamic studies was initially undertaken in the investigation of patients with NLUT by Comarr (1957) using diuresis-induced natural filling. Comar demonstrated an increase in bladder capacity and decreases in bladder pressures during natural filling when compared with retrograde filling CMG. Similar investigations of spinal cord injury (SCI) patients by Tsiju et al. (1960) demonstrated increased phasic detrusor overactivity associated with incontinence during natural filling. Today it is a well-established method for investigating lower urinary tract function under the conditions of normal daily activities. Ambulatory UDS has its greatest value in patients in whom conventional UDS is not suitable or for those who are unable to reproduce the symptoms in question.

In 2000, the ICS published guidelines for the performance of ambulatory UDS (van Waalwijk van Doorn et al., 2000). Before the investigation, patients receive detailed information describing the test and the necessary preparation. Patients were instructed on how to accurately record symptoms and how to identify catheter displacement and hardware failure. A sample diary was given to record all relevant events so that UDS findings could be correlated with symptoms. Most systems employ microtip transducer catheters, which allow the most mobility. These are placed transurethrally to record bladder pressure and transrectally to record abdominal pressure. These catheters are firmly secured to the patient and are connected to a portable recording device. Some systems contain a third channel that can be used for measuring urinary leakage objectively using an absorbent electronic (capacitance change) nappy pad (Robertson and Neil, 1998). This allows accurate data to be obtained on the relationship of urinary leakage to detrusor activity. Home uroflowmetry units are also available. Ambulatory UDS tracings are analyzed after completion of testing, and this can be a time-consuming process depending on the length of the study. This must be done with great care and frequent quality checks to make sure that the urethral and abdominal catheters are properly transducing pressure (e.g., using cough tests). In addition, the reader must be able to identify physiologic artifacts (after contractions and aberrant rectal pressures) and technical artifacts (movement or variation in pressure and lack of balance in transducer lines), which could impact the interpretation of the study. The ambulatory study should be designed to reproduce symptoms. For example, if the patient complains of stress incontinence, a standard protocol of exercises can be performed and recorded (e.g., jumping up and down, squatting, coughing).

Clinical Utility of Ambulatory Urodynamics

Ambulatory urodynamic monitoring (AUM) may be considered as a second-line tool to investigate lower urinary tract symptoms and dysfunction, when conventional laboratory UDS are inconclusive (Digesu et al., 2017). This clinical utility of ambulatory UDS is still debated, and its role in clinical practice continues to need further elucidation. Proponents of ambulatory monitoring believe that it will capture more realistic or physiologic observations, for example incontinence episodes (Hosker et al., 2009). It attempts to increase sensitivity by taking place over a longer time frame and providing a longer time for abnormalities (i.e., detrusor overactivity) to manifest. When deciding to perform AUM in clinical practice, consideration of how the results of the study will alter or direct treatment should be made. AUM has been most commonly used to diagnosis the cause of urinary incontinence, but has also been applied to the diagnosis of male BOO and NLUTD. However, AUM is not without limitations. Aside from obvious potential technical challenges, Rosier et al. (2013) noted that there are no published data on the reproducibility or test-retest differences of AUM studies or reports that evaluate the investigator dependence on the posttest analysis of recorded data. Further, a Cochrane review looking for randomized or quasi-randomized trials did not show adequate evidence that one technique of UDS was superior to the other (Glazener and Lapitan, 2012).

It has been shown that ambulatory monitoring detects more actual incontinence in symptomatically incontinent patients than retrograde filling CMG (Cassidenti and Ostergard, 1999). Dokmeci et al. (2010) prospectively classified incontinent women into three groups (urgency incontinence, stress incontinence, and mixed incontinence) using the UDI-6 questionnaire. Both conventional UDS and ambulatory UDS were prospectively performed. Overall, ambulatory UDS findings matched the classification in 77.3% of women, compared with 6.8% using conventional UDS ($P = 0.001$). The authors suggested that conventional UDS has a higher false-negative rate than conventional UDS. It is important to note that, during this study, the conventional UDS were only performed in the supine position (and then the seated position) but not in the standing position, which is often recommended. Another limitation was that the measure of incontinence during ambulatory UDS was only based on the patient-controlled event marker. This introduces a bias; thus the results must be interpreted cautiously.

Several studies have shown ambulatory UDS to be more sensitive than conventional CMG for the diagnosis of DO (Heslington and Hilton, 1996; Robertson et al., 1994). Radley et al. (2001) found that ambulatory monitoring revealed DO in 70 in 106 women with symptoms suggestive of DO (twice as many as conventional CMG with provocation by hand washing) and that it detected DO incontinence (DOI) in 40 of the 70 women. The observation of DOI was correlated with symptom severity, but it was not clear how many women complaining of urgency incontinence showed DO incontinence. Thus, the sensitivity is unknown. The finding of higher rates (and sensitivity) of DO found on ambulatory monitoring must be weighed against the fact that higher rates of DO were also found on ambulatory UDS in asymptomatic volunteers. The rates of DO found in asymptomatic females was noted as high as 69% versus 18% for conventional CMG (van Waalwijk van Doorn et al., 1996) and 38% versus 17% in asymptomatic men and women (Robertson et al., 1994). Thus, some degree of detrusor overactivity may be normal in the setting of a urethral catheter for a prolonged period, making some sort of standardization important.

In a review of 422 female ambulatory UDS over a 12-year period, Patravali (2007) argued for the value of the study. Patravali noted that 85% of patients complaining of urinary incontinence showed detectable leakage with a diagnosable mechanism on ambulatory study, and in 77% of 74 women with a normal CMG, ambulatory UDS diagnosed the cause of incontinence and provided “clear added value.” DO was a component in 42 of these 57 patients (76%). What is not known is exactly what is meant by “clear added value” and how treatment was affected. In a smaller study of 25 patients, Pannek and Pieper (2008) had similar findings but a more useful interpretation of those findings. They found that AUM was helpful (versus conventional UDS) in diagnosing lower urinary tract dysfunction in 72% of the evaluable examinations. However, 24% of the studies were not evaluable because of technical problems or catheter dislocation. Thus, ambulatory UDS was clinically useful in only 48% of the patients who underwent this examination. When a diagnosis was made on ambulatory UDS, successful treatment was established in 42% of the patients. However, when ambulatory UDS was not helpful and patients were treated based on clinical symptoms, 33.3% were treated successfully. Gorton and Stanton (2000) also looked at the effect of ambulatory UDS on clinical management. In a retrospective review of 71 women, there were technical difficulties in 42% of the studies with two being noninterpretable. DO was found in 45%, and nearly all patients were treated with medication. Among the remainder without DO, fewer received medication. However, fewer than one-half of those who received medication improved. The authors concluded that ambulatory UDS was not very helpful in deciding on management.

Ambulatory UDS has been used for the diagnosis of obstruction in men with LUTS and inconclusive (borderline or nondiagnostic) conventional PFS. Rosario et al. (1999) reclassified 24% of such patients as either obstructed or nonobstructed. However, Robertson et al. (1996) found no difference in the classification of patients with ambulatory versus conventional PFS.

It has been demonstrated that storage pressures in patients with NLUTD (and chronic obstruction) are lower on ambulatory, natural-fill UDS than on conventional CMG (Webb et al., 1989, 1991, 1992). Patients with poor compliance (high filling pressures) and hydronephrosis on conventional CMG were found to have normal compliance, but significant phasic neurogenic DO on ambulatory monitoring. It has been suggested that phasic neurogenic DO, not impaired compliance, may lead to upper tract deterioration in these patients. Although this may be true, it needs to be proven in a series of patients followed over time, and for now, based on available evidence, one must still conclude that significantly impaired compliance on conventional CMG is a risk factor for upper tract damage.

Martens et al. (2010) looked at 27 patients with SCI and symptoms suggestive of neurogenic DO. These patients underwent both conventional and ambulatory UDS (for 6 hours). It was reported that a greater percentage of patients were found to have neurogenic DO in the ambulatory study (92% vs. 69%, $P = 0.031$), but there was no difference in bladder pressure during the involuntary detrusor contraction. Comparing each method to the “clinical diagnosis of DO,” ambulatory UDS had a sensitivity to detect neurogenic DO of 85%, and conventional UDS had a sensitivity of 75%, but this was not significant ($P = 0.375$). The authors also found that the interindividual agreement to diagnosis neurogenic DO was higher for the conventional UDS compared with the ambulatory UDS. They did look at how the studies altered management recommendations and concluded that although ambulatory UDS did not need to be used as a standard tool for risk assessment in SCI patients, ambulatory UDS remain indicated if conventional UDS are not conclusive for treatment decisions.

VUDS are often considered the gold standard for the evaluation of patients with NLUTD (Pannek et al., 2013), but most studies in this population have compared ambulatory UDS to conventional UDS, but not VUDS. Vírseda-Chamorro et al. (2014) compared ambulatory UDS (with a single natural fill cycle) in 69 SCI patients. The patients were grouped by findings noted on fluoroscopy including having an open bladder neck at rest, DESD, and vesicoureteral reflux (in this population representing 25%, 64%, and 6% of patients, respectively). The authors found no association with ambulatory UDS findings. The only statistically significant finding was patients with an open bladder neck on VUD had a higher percentage of neurogenic DO (67%) on ambulatory UDS compared with those whose bladder neck was closed at rest (35%) ($P = 0.025$). This study also found lack of agreement in most other filling parameters when comparing other VUDS parameters to ambulatory UDS parameters. The cytometric capacity on ambulatory UDS (275 mL) aligned more closely with frequency volume chart bladder capacity (296 mL). VUD capacity was noted to be higher (416 mL). It is not clear that this information alters management or affects outcomes.

When considering the use of ambulatory UDS in the clinical evaluation of NLUTD, the possibility of autonomic dysreflexia (AD) deserves mention (Cameron, 2011). It was suggested that prolonged periods of catheterization and irritation from multiple catheters could be an issue, but the data about frequency of AD episodes and the ability to recognize and adequately manage AD has not been systematically evaluated.

Attempts have been made to modify the ambulatory urodynamic equipment needed and have shown some promising results in identifying neurogenic DO (Kim, 2010, 2012). Aside from technical advances and accuracy cost, convenience and patient experience must also be considered moving forward.

In conclusion, ambulatory UDS may be useful in a select group of patients in whom conventional UDS is nondiagnostic and the information provided would affect treatment, counseling, or follow-up. Ambulatory UDS and its interpretation are time-consuming and technically challenging. The data obtained for ambulatory UDS must be weighed against the fact that for many findings, standards, both normal and abnormal, have not been established. More data are needed on the reproducibility of ambulatory UDS. The impact that ambulatory UDS has on altering management and changing both patient-reported and objective outcomes should be

investigated across varied patient populations.

Key Point

- Ambulatory urodynamic monitoring may be useful in a select group of patients in whom conventional UDS is nondiagnostic and the information provided would affect treatment, counseling, or follow-up.

Clinical Applications of Urodynamic Studies: Evidence-Based Review and Guidelines Pertaining to Urodynamics

Thus far, we have described the technical aspects of UDS and general indications for use. In this section, we will provide an evidence-based review of UDS for different common clinical applications. In many situations, there is not enough evidence in the literature to conclude how useful UDS is for a particular case, and as such, its use should be based on a clinical impression. Nevertheless, there are some instances and indications in which the evidence is strong enough to provide guidance as to how useful UDS will be. Over the past many years, there has been a push to establish clinical guidelines.

Guidelines

In 2012, the AUA/SUFU produced a guideline for UDS (Winters et al., 2012). The AUA makes efforts to periodically review and confirm the validity of guidelines, but this guideline has not been reconfirmed at the time of this writing. The AUA/SUFU Guideline Panel believes that UDS guidelines do not necessarily establish the standard of care, but rather should encourage compliance by practitioners with current best practices related to the condition being treated. Individual health care providers must take into account individual patient situations including patient willingness to be treated, variations in resources, and patient tolerances, needs, and preferences. The AUA/SUFU guideline on UDS made a total of 19 statements about UDS on four disease states: SUI/pelvic organ prolapse, overactive bladder urgency urinary incontinence and mixed urinary incontinence, neurogenic bladder, and lower urinary tract symptoms. The AUA/SUFU guideline was “intended to review the literature regarding urodynamic testing in common lower urinary tract conditions and assist clinicians in the proper selection and application of urodynamic tests, following an appropriate evaluation and symptom characterization.” This format has an advantage when considering a specific set of diagnostic tests, but disease-specific guidelines may have some practical advantage for the clinician to understand when and how to use a test for a condition-specific question.

An example of a condition-specific guideline is the new AUA/SUFU guideline on **surgical treatment of SUI,** which contains two statements pertaining to UDS (Kobashi et al., 2017). The AUA/SUFU guideline on overactive bladder and bladder pain syndrome/interstitial cystitis are other disease-specific guideline from the AUA that comments on UDS and the role in each condition (Gormley et al., 2015; Hanno et al., 2015).

In fact, there are a multitude of other guidelines from other agencies that are redundant and ultimately based on the same available data. The European Association of Urology (EAU) Guidelines on Urinary Incontinence also summarizes level of evidence and makes six statements about performing UDS in neurologically intact adults with urinary incontinence (Lucas et al., 2013). This guideline had been recently updated, but the ensuing updates have not changed the recommendations regarding UDS (Burkhard et al., 2017). These guidelines will be explored later.

Overall, the development of most guidelines usually begins with a systematic review. This gives the committee a basis to come up with evidence when possible to support their recommendations. The work is often presented with a grading system. This give the reader an assessment of the strength of each recommendation and the strength of data used to make that determination. For example, the AUA guidelines on UDS utilize the Oxford system. This system gives a grade A recommendation usually if it depends on consistent level 1 evidence. This often means that the recommendation is effectively mandatory and placed within a clinical care pathway. A grade B recommendation usually depends on consistent level 2 or 3 evidence studies, or “majority evidence” from randomized controlled trials. A grade C recommendation usually depends on level 4 evidence studies or “majority evidence” from level 2 or 3 studies or from “expert opinion.”

Guidelines are based on best evidence available to experts; however, they do not necessarily result in differences or improvement in outcomes. They should not replace clinical expertise for individual patients. They are not meant to mandate care or be considered a legal standard.

We will specifically address four areas in which UDS is commonly used for evaluation and enough evidence exists to make valid conclusions or recommendations: women with SUI, men and women with LUTS, and NLUTD.

Evaluation of Women With Stress Incontinence

For the past decade, it has generally been felt that for women with pure SUI without urgency symptoms who empty normally and demonstrate SUI on physical examination, UDS will not provide much useful information. For example, in the SISTEr trial, a randomized trial comparing the efficacy of Burch procedure versus pubovaginal sling in 655 *selected* women with pure or predominate SUI and no obvious emptying problems, UDS, including ALPP and presence of DO, added little to help determine surgical outcomes with respect to efficacy (Nager et al., 2008) or postoperative voiding dysfunction (Lemack et al., 2008). In 2006, in the UK, the National Institute of Health and Clinical Excellence (NICE) issued guidelines that urodynamics was recommended before surgery for urinary incontinence only if there is a clinical suspicion of DO, or if there has been previous surgery for stress incontinence or anterior compartment prolapse, or if there are symptoms suggestive of voiding dysfunction. In the past several years, there have been two randomized controlled trials designed to answer the question of how useful UDS is in the evaluation of women with straightforward SUI.

The Value of Urodynamic Evaluation (ValUE) Trial was a multicenter, randomized, noninferiority trial involving women with uncomplicated, stress-predominant urinary incontinence who were planning to undergo surgery, to determine whether outcomes at 1 year among women who underwent only an office evaluation were inferior to those among women who also underwent preoperative urodynamic studies (Nager et al., 2012). The study included a select group of women with pure or stress-predominant SUI based on a validated questionnaire, a PVR of less than 150 mL, a negative urinalysis or urine culture, and urethral mobility with a positive provocative stress test. Women with previous surgery for incontinence, a history of pelvic irradiation, pelvic surgery within the previous 3 months, and significant anterior or apical pelvic-organ prolapse were excluded. A total of 630 women were equally randomized to office evaluation plus UDS versus office evaluation alone. The primary outcome was surgical treatment success measured as a reduction in the Urogenital Distress Inventory score from baseline to 12 months of 70% or more and a Patient Global Impression of Improvement response of “very much better” or “much better” at 12 months. The proportion in which treatment was successful was 76.9% in the urodynamic-testing group versus 77.2% in the evaluation-only group (difference, −0.3 percentage points; 95% confidence interval [CI] −7.5 to 6.9), which was consistent with noninferiority. The authors did note that based on UDS, 18 women had the type of surgery changed from transobturator to retropubic midurethral sling (12) or from retropubic to transobturator sling (6). It is not clear if these changes affected outcomes. The authors concluded that for women with uncomplicated, demonstrable SUI, preoperative office evaluation alone was not inferior to evaluation with urodynamic testing for outcomes at 1 year. In a follow-up study, the authors found that for patients who underwent UDS, physician confidence for the diagnosis of ISD, OAB-wet and dry (presumably detrusor overactivity), and voiding phase dysfunction, but not SUI, increased (Zimmern et al., 2014). However, this did not correlate with treatment success.

In another study to investigate the value of urodynamics before SUI surgery, van Leijsen et al. (2013) conducted a multicenter diagnostic cohort study with an embedded noninferiority randomized controlled trial in six academic and 24 nonacademic Dutch hospitals. All women in the trial had SUI or stress-predominant mixed incontinence and underwent UDS. Those who had UDS that were discordant with clinical assessment (SUI was not confirmed, detrusor overactivity, weak flow, elevated post void residual, small cystometric maximum capacity, or a reduced bladder sensation) were then randomly allocated to receive either immediate surgery or individually tailored therapy based on UDS. Possible treatment options included anticholinergics for detrusor overactivity, prolonged pelvic floor exercises or bladder training in cases of dysfunctional voiding, a pessary, expectant management, intravesical botulinum toxin injections, or pretibial nerve stimulation at the physician's discretion. Of the 578 included women, 268 women (46%) had urodynamic findings that were discordant with clinical history and physical examination. Consent for randomization was obtained from 126 patients. Of the patients randomized to individualized treatment, 57 of 62 received surgery as the initial treatment. The mean improvement on the Urogenital Distress Inventory UI subscale was 39 points (±25) in the group who received individually tailored treatment compared with 44 points (±24) in the group receiving immediate surgery. The difference in mean improvement was 5 points in favor of the group receiving immediate surgery, confirming noninferiority for either one of the strategies. Subjective cure as measured with the Urogenital Distress Inventory and objective cure as measured with the stress test and bladder diary were no different between the two arms. In the surgery group, subjective cure was 43 of 58 (74%) and in the individual treated group 42 of 56 (75%) (relative risk 0.99, 95% CI 0.80 to 1.23). Objectively cured were 37 of 38 women (97%) in the surgery group and 33 of 34 women (97%) in the individual treated group (relative risk 1.00, 95% CI 0.93 to

1.09). The authors concluded that in women with uncomplicated SUI, an immediate midurethral sling operation is not inferior to individually tailored treatment based on urodynamic findings.

These two well-done studies suggest that UDS is not essential before surgical treatment of stress-predominant urinary incontinence in women when SUI is seen clinically. However, many women with SUI who are considering surgical correction have mixed symptoms or emptying difficulties, and it is here that UDS probably has its most significant role for female SUI. In addition, previous studies have found significant variation of the predictive value of symptoms in identifying the three UDS observations of urodynamic SUI, DOI, and mixed urinary incontinence (Agur et al., 2009; Harvey and Versi, 2001; Homma, 2002). This variation is probably explained by nonhomogeneous patient populations and an inconsistency in the clinical and UDS diagnosis between the studies.

We believe that UDS does have a valuable and definitive role in the preoperative evaluation of some women with SUI and significant urgency symptoms. In fact, several studies have shown excellent cure rates for both stress and urgency symptoms in women with urodynamic SUI and a normal CMG (no DO) for pubovaginal sling (Chou et al., 2003; Osman, 2003), Burch procedure (Osman, 2003), and tension-free vaginal tape (Rezapour and Ulmsten, 2001). It should be noted that the trials that have shown no difference in success of treatment with or without DO were primarily done in patients with stress-predominant SUI. The presence or absence of DO in women with more significant urgency symptoms may play a more significant role in predicting outcomes.

Based on a thorough review of the literature, the AUA Urodynamics Guideline Panel has made the following statements (Winters et al., 2012):

- “Clinicians who are making the diagnosis of urodynamic stress incontinence **should** assess urethral function (Recommendation; Evidence Strength: Grade C).” The committee recommends that if UDS is performed, an assessment of urethral function (e.g., ALPP or MUCP) should be performed. This seems reasonable as an ALPP may for some surgeons affect the type of surgery performed, as inferior outcomes have been found for some procedures in patients with low ALPP and/or MUCP.

- “Surgeons considering invasive therapy in patients with SUI **should** assess PVR urine volume (Expert Opinion).” An elevated PVR may prompt a change in treatment for additional testing such as UDS.
- “Clinicians **may** perform multichannel UDS in patients with both symptoms and physical findings of SUI who are considering invasive, potentially morbid, or irreversible treatments. (Option; Evidence Strength: Grade C).” This statement allows the clinician to make a decision of the selective use of preoperative UDS based on the patient's symptoms, how the study will influence choice of surgery, and the degree of confidence that the surgeon has in his or her diagnosis.
- “Clinicians **should** perform repeat stress testing with the urethral catheter removed in patients suspected of having SUI who do not demonstrate this finding with the catheter in place during urodynamic testing (Recommendation; Evidence Strength: Grade C).” It is well established that some women will not demonstrate SUI with a catheter in place. This maneuver is especially important in women who do not demonstrate SUI on physical examination.
- “In women with high-grade POP but without the symptom of SUI, clinicians **should** perform stress testing with reduction of the prolapse. Multichannel UDS with prolapse reduction **may** be used to assess for occult stress incontinence and detrusor dysfunction in these women with associated LUTS (Option; Evidence Strength: Grade C).” Prolapse reduction is extremely important if the demonstration of occult SUI on UDS will influence the type of prolapse surgery performed (i.e., a simultaneous anti-incontinence with prolapse repair).

Women can develop SUI after prolapse surgery, and different options exist for managing the urethra at the time of prolapse surgery or trying to prevent incontinence. Two randomized controlled trials, with and without concomitant anti-incontinence surgeries, have suggested that there is more de novo SUI in women that have occult SUI preoperatively (Visco et al., 2008; Wei et al., 2012). Therefore, the surgeon may elect to “risk-stratify” women pre–prolapse surgery by looking for occult incontinence, and UDS with reduction is one way to assess these women; however, this is a commonly debated topic (Serati et al., 2015).

The ICS committee on pathophysiology of urinary incontinence (2016) in the 6th edition of *Incontinence* feels it is clear that UDS can add some information in women undergoing pelvic organ prolapse surgery and could facilitate patient counseling, but note that there is no compelling evidence that surgical outcomes are determined by the test.

Some studies have suggested that office evaluation with reduction may perform as well as UDS in determining the presence or absence of occult incontinence (Hwang et al., 2018). van der Ploeg et al. (2018) found that UDS were more likely to find SUI compared with office evaluation, but it did not have added value in predicting postoperative SUI. Though the office evaluation had a higher diagnostic odds ratio, the confidence intervals overlapped and the author sites lack of power (suggested on a post hoc calculation) and different baseline characteristics as limitations of the study.

The AUA guidelines on the surgical treatment of SUI also make statements about UDS (see Guidelines section earlier in this chapter) (Kobashi et al., 2017). They are as follows:

- Physicians may omit urodynamic testing for the index patient desiring treatment when SUI is clearly demonstrated (conditional recommendation; grade B recommendation)
- Physicians may perform urodynamic testing in nonindex patients (expert opinion). Urodynamic testing may be performed at the clinician's discretion in certain nonindex patients, including but not limited to patients with the following:
  - History of prior anti-incontinence surgery
  - History of prior POP surgery
  - Mismatch between subjective and objective measures
  - Significant voiding dysfunction
  - Significant urgency, UUI, OAB, MUI with significant urgency component

- Elevated PVR per clinician judgment
- Unconfirmed SUI
- NLUTD

The EAU Guidelines on Urinary Incontinence, though not specific to women with SUI, start by suggesting that when performing UDS there is adherence to *good urodynamic practice standards* as described by the ICS (Nambiar et al., 2018; Rosier et al., 2017b). They then make a number of practical recommendations about UDS, which are generally consistent with the AUA guidelines.

Clinicians carrying out UDS in neurologically intact patients with urinary incontinence should:

- Attempt to replicate the patient's symptoms (strength rating: strong)
- Check recoding for quality control (strength rating: strong)
- Interpret results in the context of the clinical problem (strength rating: strong)
- Remember there may be physiologic variability within the same individual (strength rating: strong)
- Not routinely carry out urodynamics when offering treatment for uncomplicated SUI (strength rating: strong)
- Perform urodynamics if the findings may change the choice of invasive treatment (strength rating: weak)
- Not routinely carry out urethral pressure profilometry or leak point pressure to grade severity of incontinence (strength rating: strong)

Both AUA and EAU guidelines give the clinician the discretion to perform UDS before surgery, based on the individual patient, clinical scenario, and whether UDS will ultimately affect the choice of treatment (the latter varies based on the individual clinician).

The National Institute for Health and Care Excellence (NICE) (National Collaborating Centre for Women's and Children's Health, UK, 2013) and the Canadian Urological Association (Bettez et al., 2012) also have guidelines on “urinary incontinence” (not necessarily SUI incontinence in women) that comment on or make statements pertaining to UDS. Syan and Brucker (2016) published “Guidelines of Guidelines” for urinary incontinence. A part of this review was analyzing the statement of these various publications and conclude the statements related to UDS agree that the invasive UDS are not needed before conservative treatments, but may be used if the data may alter treatment recommendation and management (e.g., before more invasive therapies). Overall there is agreement to recommend UDS if urinary incontinence is recurrent after invasive treatments have been unsuccessful. Also, the authors note there is considerable redundancy in available guidelines.

Evaluation of Men and Women With Lower Urinary Tract Symptoms

The cause of LUTS in men and women is multifactorial comprising at least four conditions 1) BOO, 2) detrusor underactivity, 3) detrusor overactivity, and 4) “sensory urgency” (Blaivas, 1988). Often storage symptoms of frequency and urgency accompany voiding symptoms of decreased force of stream and hesitancy. Urgency incontinence can also occur as a result of DO with or without BOO. LUTS are common among men of 50 years and older. It has been established that coexistence of BOO and DO in men increases with age and with the degree of BOO (Oelke et al., 2008; Vesely et al., 2003). In such cases, UDS can be helpful to establish the underlying bladder and or bladder outlet abnormality.

Noninvasive testing such as PVR and uroflowmetry can be helpful in the evaluation of men and women with LUTS and may also prompt further invasive UDS testing. The AUA Urodynamics Guideline (Winters et al., 2012) states that “Clinicians may perform PVR in patients with LUTS as a safety measure to rule out significant urinary retention both initially and during follow-up (Clinical Principle).” Although it is true that PVR cannot differentiate between obstruction and nonobstructive conditions (e.g., detrusor underactivity) and that there is no agreed upon definition of exactly what volume constitutes an elevated PVR, most urologists would agree with this statement. The guideline also states that uroflow may be used by clinicians in the initial and ongoing evaluation of male patients with LUTS that suggest an abnormality of voiding/emptying (Recommendation; Evidence Strength: grade C). Like PVR, an abnormal uroflow cannot differentiate between obstruction or detrusor underactivity, but it can be helpful in instituting or not instituting certain therapies or in prompting further testing.

The question of how much help UDS is in the evaluation and treatment of male LUTS has been debated for years. How necessary is a diagnosis of BOO before transurethral prostate resection, for example? The answer is dependent on how comfortable the clinician is making a diagnosis and treating with less invasive and less definitive testing. Few would argue that to institute an α-receptor blocker for the treatment of LUTS in a man with relatively normal bladder emptying, UDS is not required. However, as the scenario becomes more complex and the treatment more invasive and potentially morbid, a precise diagnosis will be helpful in many cases. Often it is ultimately up to the clinician to decide how much information is useful or necessary to make a treatment decision and properly counsel patients.

It is well documented that in men with BOO, surgery such as transurethral prostate resection (by any means) reduces obstruction and relieves symptoms. However, storage symptoms such as urgency frequency and urgency incontinence persist in about one-third of cases. It has been shown that when storage symptoms are associated with DO and BOO, UDS can help predict resolution of those symptoms. In such a scenario, storage symptoms have a higher likelihood of resolving with intervention (e.g. TURP) when DO occurs as a single terminal IDC rather than continuous or sporadic IDCs (Kageyama et al., 2000). Such information can be quite valuable when counseling patients. For example, given the same UDS presentation of BOO plus continuous IDCs, a patient primarily concerned with his inability to empty may opt for surgery, whereas a patient who is primarily concerned about OAB symptoms may not.

As for the utility of UDS before surgical treatment or no treatment of LUTS thought to be secondary to BPH, the literature is mixed with several studies supporting its necessity (Javle et al., 1998; Porru et al., 2002; Rodrigues et al., 2001; Thomas et al., 2004). Others have concluded that UDS are not necessary (Kanik et al., 2004; Pannek et al., 1998) or necessary only in inconclusive cases (Ignjatovic, 1997). Other reviews have suggested that UDS has some, but not strong predictive value for treatment outcomes (Abrams et al., 2001; Brucker and Jaffe, 2009; Clemens, 2003; Homma, 2001). Another review by Bhargava et al. (2004) concluded that conventional urodynamic studies are useful in providing preoperative information about detrusor function, and to exclude patients less likely to benefit from prostate surgery. Despite this, some regard the need for performing urodynamic evaluation routinely, before transurethral resection of the prostate, as still controversial. This led the experts at the 6th International Consultation on New Developments in Prostate Cancer and Diseases to conclude that although almost all evidence for the advantages of UDS before invasive therapy for benign prostatic obstruction (BPO) is level 3 (good-quality retrospective "case-control studies" or "case series"), the quantity of evidence allows a grade B recommendation (Abrams et al., 2006). In a similar statement, **the AUA/SUFU Urodynamics Guideline states that "Clinicians should perform pressure-flow studies in men when it is important to determine if urodynamic obstruction is present in men with LUTS, particularly when invasive, potentially morbid, or irreversible treatments are considered (Standard; Evidence Strength: grade B)** (Winters et al., 2012).

The EAU Guidelines on the Assessment of Non-neurogenic Male Lower Urinary Tract Symptoms Including Benign Prostatic Obstruction directly addresses when pressure-flow studies should be performed (Gratzke et al., 2015). The recommendations are as follows:

- Pressure-flow studies **should be performed only in individual patients for specific indications** before surgery or when evaluation of the underlying pathophysiology of LUTS is warranted (level 3, grade B recommendation).
- Pressure-flow studies **should be performed** in men who have had previous unsuccessful (invasive) treatment for LUTS (level 3, grade B recommendation).
- When considering surgery, pressure-flow studies **may be used** for patients who cannot void greater than 150 mL (level 3, grade C recommendation).
- When considering surgery in men with bothersome predominantly voiding LUTS, pressure-flow studies **may be performed** in men with PVR greater than 300 mL (level 3, grade C recommendation).
- When considering surgery in men with bothersome predominantly voiding LUTS, pressure-flow studies **may be performed** in men older than 80 years of age (level 3, grade C recommendation).
- When considering surgery in men with bothersome

> predominantly voiding LUTS, pressure-flow studies **should be performed** in men age younger than 50 years of age (level 3, grade B recommendation).

Chua et al. assessed available guidelines of non-neurogenic male LUTS and found pressure-flow urodynamics generally as an optional test (Chua et al., 2015). The recommendation for uroflow and PVR were also usually “optional,” but some guidelines consider these tests to be “recommended” and even mandatory in one case.

Most of the time when BOO is treated it is done so because of symptoms. However, “asymptomatic” BOO, if not relieved in time, may lead to progression of the disease and affect organ function. Historically most attention was paid the backpressure effects of obstruction on the kidneys (from high voiding pressures and/or impaired compliance). However, it is now known that that BOO affects bladder function, leading to structural changes. Because the changes may eventually become irreversible, some would argue that management should be directed toward early relief of significant obstruction (Brierly et al., 2003; Flanigan et al., 1998; Lu et al., 2000). More longitudinal studies are needed. **However, at this time, a critical level of obstruction (e.g., based on the BOOI) has not been defined. There are no evidence-based studies to suggest when surgical relief is indicated to prevent bladder decompensation. However, many papers have shown that if there is no evidence of obstruction on PFS, the results of surgical relief are not as favorable** (Porru et al., 2002; Thomas et al., 2004)**. Significantly impaired compliance remains the only “absolute urodynamic indication” for treating BOO.**

There are times when it may be important to diagnose DO or more importantly impaired compliance that is associated with LUTS. In addition to BOO, conditions such as radiation cystitis and certain inflammatory diseases (e.g., tuberculosis) can cause impaired compliance. Impaired compliance, however, can only be diagnosed by CMG. In such cases, the diagnosis of impaired compliance can result in the institution of therapy independent of symptoms. Thus, in cases in which impaired compliance is suspected, we recommend UDS testing. This is consistent with the following AUA/SUFU Urodynamics Guideline statements:

> - “Clinicians may perform multichannel filling cystometry when it is important to determine if altered compliance, DO or other

> urodynamic abnormalities are present (or not) in patients with urgency incontinence in whom invasive, potentially morbid, or irreversible treatments are considered. (Option; Evidence Strength: Grade C)"
> • "Clinicians may perform multi-channel filling cystometry when it is important to determine if DO or other abnormalities of bladder filling/urine storage are present in patients with LUTS, particularly when invasive, potentially morbid, or irreversible treatments are considered (Expert Opinion)."

The AUA/SUFU OAB guidelines also include UDS in a statement related to diagnostic testing (Gormley et al., 2015). **"UDS… are not recommended in the initial diagnostic workup of the uncomplicated OAB patient." Here latitude is given to the clinician when the OAB patient is complicated or refractory to multiple OAB treatments. In these cases, the use of UDS depend on patient history and presentation and clinician judgment.**

As in men, women with emptying problems (poor emptying and/or voiding symptoms) may benefit from UDS with voiding pressure-flow studies. This can help differentiate obstruction from impaired contractility. UDS is particularly helpful when the cause of obstruction is not obvious. Anatomic obstruction (high-grade prolapse, incomplete emptying after incontinence surgery, urethral mass) is usually obvious. However, functional obstruction like dysfunctional voiding or primary bladder neck obstruction is not obvious on physical examination or endoscopy and requires evaluation during voiding. We agree with the AUA/SUFU Urodynamics Guideline statement that "Clinicians may perform pressure-flow studies in women when it is important to determine if obstruction is present. (Recommendation; Evidence Quality: Grade C)" (Winters et al., 2012). We find VUDS to be particularly helpful as it can diagnose and localize obstruction (see Videourodynamics section earlier in this chapter).

Evaluation of Neurogenic Lower Urinary Tract Dysfunction

NLUTD usually presents clinically as incontinence and/or inability to empty the bladder. Incontinence may be of bladder origin (detrusor overactivity or impaired compliance) or sphincter origin. Poor emptying can also be of bladder origin (neurogenic detrusor underactivity or neurogenic acontractile detrusor) or sphincter origin (dyssynergia). In addition to symptomatic presentation, NLUTD can present as upper urinary tract decompensation with hydroureteronephrosis and renal insufficiency without bothersome symptoms. The goal of management in these patients is to prevent upper tract decompensation and relieve symptoms. A specific understanding of the pathophysiology of the condition in each individual is essential for the correct choice of therapy (Rivas and Chancellor, 1995; Stohrer, 1990; Stohrer et al., 1994). **UDS probably has its most important role in the evaluation and management of patients with neurogenic voiding dysfunction.**

The aims of therapy for NLUTD are to achieve physiologic filling (and if possible voiding) conditions and to control symptoms and create a management situation acceptable to the patient in daily life. Much of the evidence base for management of the lower urinary tract in the neurogenic patient consists of level 3 or lower evidence. This is primarily because of the potential negative consequences of untreated neurogenic dysfunction. As such, randomized controlled trials are thought by many to be dangerous and unethical. Because prolonged periods of elevated detrusor pressure during bladder filling or abnormally prolonged elevated pressures during voiding have been found to put the upper urinary tract at risk (Kurzrock and Polse, 1998; McGuire et al., 1996; Tanaka et al., 1999), the primary aim of therapy in patients with such problems is conversion to a low-pressure bladder during filling, even if this leads to incomplete emptying and the need to supplement emptying with catheterization. Adequate therapy depends on whether the detrusor is overactive or has reduced compliance, and only urodynamics can answer these questions unequivocally. In addition to the prevention and amelioration of upper and lower urinary tract abnormalities/decompensation, timely and adequate diagnosis of DO and impaired compliance is thought to be of paramount importance for the patient's quality of life (Bomalaski et al., 1995; Cardenas et al., 1995; Stohrer, 1990, Stohrer et al., 1994). UDS is also essential for assessing the response to treatment and following any sequelae of the disease and its management (Hosker et al., 2009).

Another test that has been described in neurogenic patients is the “ice water test” (IWT). This was first described in 1957, but there is still no generally agreed upon algorithm of how to perform this test in clinical practice (Bors and Blinn, 1957). It has been suggested that instillation of cold water will differentiate between an upper (positive test) and lower (negative test) motor neuron lesion (Kozomara et al., 2018). The ice water instilled into the bladder is thought to elicit a C-fiber–mediated reflex. Bladder temperature receptors can elicit a spinal reflex contraction of the detrusor, a reflex that is normally inhibited by supraspinal centers. If an upper motor neuron lesion interrupts this inhibitory pathway, the result is a reflex contraction, whereas if the lesion is a lower motor neuron, the contraction does not occur. Most studies show value to differentiation between reflexic and areflexic neurologic bladder (Apostolidis et al., 2017). The ICS considers it an option test that needs to be interpreted in the context of all other available data but that should not precede regular UDS.

Not all NLUTD requires UDS before observation or treatment. Conditions in which high storage pressures are not suspected (e.g., urgency incontinence in a poststroke patient or a woman with multiple sclerosis and a low PVR) can often be managed initially without UDS. But in cases in which the neurologic condition/lesion can cause potentially harmful storage situations (spinal cord injury, myelomeningocele), UDS is essential both before treatment and in ongoing follow-up of the condition and to monitor the response to treatment. In the middle are situations in which UDS can be helpful in guiding management (e.g., men with possible BPO and Parkinson's disease or multiple sclerosis). The AUA/SUFU Urodynamic Guidelines contain five very important and practical statements regarding UDS in NLUTD (Winters et al., 2012):

- Clinicians should perform PVR assessment, either as part of complete urodynamic study or separately, during the initial urologic evaluation of patients with relevant neurologic conditions (e.g., spinal cord injury, myelomeningocele) and as part of ongoing follow-up when appropriate (Standard; Evidence Strength: grade B).
- Clinicians should perform a complex CMG during initial urologic evaluation of patients with relevant neurologic conditions with or without symptoms and as part of ongoing follow-up when appropriate. In patients with other neurologic diseases, physicians may consider CMG as an option in the urologic evaluation of patients with LUTS (Recommendation; Evidence Strength: grade C).
- Clinicians should perform pressure-flow analysis in patients

with relevant neurologic disease with or without symptoms or in patients with other neurologic disease and elevated PVR or urinary symptoms (Recommendation; Evidence Strength: grade C).

- When available, clinicians may perform VUDS in patients with relevant neurologic disease at risk for NLUTD or in patients with other neurologic disease and elevated PVR or urinary symptoms (Recommendation; Evidence Strength: grade C).
- Clinicians should perform EMG in combination with CMG with or without pressure-flow studies in patients with relevant neurologic disease at risk for NLUTD or in patients with other neurologic disease and elevated PVR or urinary symptoms (Recommendation; Evidence Strength: grade C)

The EAU has also produced a specific guideline on NLUTD (Groen et al., 2016; Pannek et al., 2013). This comprehensive guideline has a section with recommendations about UDS in neurogenic patients. The EAU guideline suggests the following:

- Noninvasive testing is mandatory before invasive UDS is planned (grade A).
- UDS investigation is necessary to detect and specify LUTS dysfunction (grade A).
- Same-session repeat measurement can be helpful in clinical decision making (grade C).
- VUDS is the gold standard for invasive UDS in neurourologic patients (grade A).
- A physiologic filling rate with body-warm saline should be used (grade A).
- Specific uro-neurophysiologic tests (e.g., electromyography, nerve conduction studies of pudendal nerve) are elective procedures (grade C).

The EAU Guideline on Neurogenic Lower Urinary Tract Dysfunction compliments other available guidelines (Groen et al., 2016; Pannek et al., 2013). The suggestions here are similar to the AUA/SUFU guidelines on UDS. There is a suggestion to start with noninvasive testing before invasive UDS, utilizing VUDS in neurogenic patients. However, the EAU guidelines make a few technical suggestions dealing with the technical aspects of the test.

Key Points

- There is mounting evidence that UDS is not essential before surgical treatment of stress-predominant urinary incontinence in women when SUI is seen clinically.
- According to the AUA guidelines on UDS, perform pressure-flow studies in men when it is important to determine if urodynamic obstruction is present in men with LUTS, particularly when invasive, potentially morbid, or irreversible treatments are considered.
- As in men, women with emptying problems (poor emptying and/or voiding symptoms) may benefit from UDS with voiding pressure-flow studies. This can help differentiate obstruction from impaired contractility. UDS is particularly helpful when the cause of obstruction is not obvious.
- UDS probably has its most important role in the diagnosis and management of patients with neurogenic voiding dysfunction.

Future Directions

Invasive urodynamics have been a valuable research tool to gaining understanding of lower urinary tract function and dysfunction. The tools have allowed an understanding of how therapeutic interventions alter the lower urinary tract. We now understand how to diagnose lower urinary tract dysfunction and, in some cases, can predict outcomes with the information UDS give us. We also need to consider how UDS can alter our clinical decision making, impact our patients' understanding and choices, phenotype patients, and perhaps predict long-term management strategies.

New directions in urodynamics also include new methods and techniques, technology, and cut points. These tools are investigated to give us an understanding if they have a role in the UDS armamentarium. For example, many noninvasive tests have been used to assess the voiding phase of men. In a systematic review, Malde et al. (2017) looked at the ability of these noninvasive tests to diagnosis male BOO. These include detrusor wall thickness (median sensitivity 82%, specificity 92%); near-infrared spectroscopy (NIRS) (median sensitivity 85%, specificity 87%); the penile cuff test (median sensitivity 88%, specificity 75%); uroflowmetry with a maximum flow rate less than 10 mL/s (median sensitivity 68%, specificity 70%); and intravesical prostatic protrusion greater than 10 mm (median sensitivity 68%, specificity 75%). The extensive review of available literature, however, concluded that there are current limitations in the evidence base such as issues with heterogeneity of definitions and threshold values used, small sample sizes, and lack of stringent methodologic standards. Further, it is complicated because to really understand each tool, the clinician may need to consider the efficacy and value of combining tests together.

There is also some data about new methods of assessing bladder storage (Farag and Heesakkers, 2011). Ultrasound parameters (e.g., bladder wall thickness, detrusor wall thickness, bladder weight) have also been examined as some potential surrogates for DO in patients with OAB. The potential role of NIRS, an optical technology capable of measuring the changes in concentration of bladder wall chromophores (i.e., oxyhemoglobin and deoxyhemoglobin), is also assessed. Here it is used to look at the presence of DO. NIRS detects the hemodynamic changes caused by involuntary detrusor contractions in real time, but motion artifacts currently limit its clinical applicability. Finally, laboratory biomarkers (i.e., NGF) also show substantial correlation with DO/OAB, but currently lack specificity. In a review of methods for the storage phase, Farag and Heesakkers (2011) concluded that the methods “still have limitations and cannot be applied reliably in routine clinical practice.” Further, other than DO, the methods are unable to quantify other important parameters of bladder storage function. Thus, the conclusion was that filling cystometry remains the gold standard tool in the diagnosis of bladder storage disorders.

Another newer tool that has been used to help understand neuronal control of the micturition cycle is functional magnetic resonance imaging (fMRI). fMRI works by quantifying the paramagnetic properties of oxygenated and deoxygenated hemoglobin, which correlate with neuronal activity as it relates to changes in blood flow (Krhut et al., 2012). It is mentioned in this chapter as it can be paired with concurrent UDS during filling and micturition. This has been carried out in normal controls and patients with dysfunction (i.e., OAB) (Shy et al., 2014; Komesu et al., 2011). The technique can identify areas and the sequences of brain network activation as they relate to the micturition cycle. This pairing of UDS and fMRI is still developing as a research tool, but it may someday have more clinical implications.

Urinary Incontinence and Pelvic Prolapse

Epidemiology and Pathophysiology

Gary E. Lemack MD, Maude Carmel MD

Definition and Classification of Urinary Incontinence

Introduction and Overview of the Lower Urinary Tract

Urinary incontinence (UI) profoundly affects millions of women and men, their partners, and their family members and results in billions of dollars in direct and indirect health care expenses. Although the number of visits and procedures related to UI has steadily increased throughout the past several decades, the number of symptomatic yet undiagnosed women remains substantial, suggesting significant under-reporting (Miller et al., 2009). One study of a middle-aged managed care population of women noted that 53% of all women who were found to have no mention of UI on their clinical office visit in fact reported UI in the last year when directly questioned, and 37% reported UI within the last week. Moreover, more than half classified it as moderate to severe (Wallner et al., 2009). Therefore, although great advances have been made in medical and surgical treatments, there remains a great challenge for clinicians to identify women with UI, appropriately characterize it, and initiate a discussion of management strategies.

The lower urinary tract (LUT) is composed of the bladder and urethra, supported by a complex system of neural innervation and musculofascial support in the lower pelvis. Lower urinary tract symptoms (LUTS), including UI, can develop as a result of anatomic abnormalities in the lower urinary tract that may be at the macroscopic, microscopic, or ultrastructural level. Such abnormalities include functional alterations in the various components of the LUT (e.g., the urothelium, detrusor musculature, sphincteric unit) or abnormalities of the surrounding structures affecting the ability of the LUT to perform its normal functions. Those normal functions, which principally involve storing urine at low intravesical pressures and expelling urine at socially appropriate and convenient times, may indeed be inexorably influenced by a variety of coexisting urologic and nonurologic conditions, demographic/environmental risks, lifestyle choices, and genetic factors.

Signs, Symptoms, and Urodynamic Observations of Urinary Incontinence

Evaluating the LUT involves distinguishing among signs, symptoms, and (urodynamic) observations. These distinctions are necessary particularly because symptoms of LUT dysfunction are often nonspecific. That is to say, varying causes of LUT dysfunction can result in very similar LUTS. Urinary urgency, for example, can be present with overactive bladder (OAB), bladder outlet obstruction (BOO), pelvic organ prolapse (POP), and interstitial cystitis/painful bladder syndrome, as well as other conditions. The extent of the diagnostic evaluation necessary to clarify the cause varies by condition, invasiveness/risk of the proposed intervention, and, to a certain extent, comfort level of the clinician and patient. Therefore, although it is safe to assume that the more definitive the diagnosis, the more effective a particular treatment strategy is likely to be, it is clear that an extensive and expensive diagnostic evaluation is not necessary in all cases to offer appropriate treatment options.

A sign of LUT dysfunction is considered one that is observable by the clinician. For the purpose of LUT dysfunction, this may include, for example, the finding of UI during a supine stress test or the finding of pelvic organ prolapse (POP) in a woman who complains of pelvic pressure. Signs are reproducible and objective.

Symptoms are the subjective report, made directly by the patient or given by a caregiver/family member, describing a condition or a change in a condition from what had been previously experienced. By their nature, symptoms are descriptive/experiential, and they may reflect noticeable alterations in the patient's perception of their LUT function. Symptoms can be self-reported, or they can be determined through the use of a variety of validated questionnaires, many of which are developed for the sole purpose of attempting to make more objective what is, at its essence, a very subjective report. Symptoms, including incontinence, do not necessarily indicate bother, which is a critical distinction to make, because quality-of-life (QoL) impact is the most common reason to intervene for LUTS. In the absence of QoL change, treatment may not necessarily be indicated. A symptom that is very bothersome to one patient may be essentially unnoticed by another.

Observations may be urodynamic or nonurodynamic. Nonurodynamic observations include, for example, information gleaned from patient-completed voiding (bladder) diaries. Urodynamic observations are specific findings made during urodynamic studies that may help in delineating the underlying physiologic basis of LUTS. Specific guidelines have been developed regarding indications for (Winters et al., 2012), and implementation of, urodynamic studies (Rosier et al., 2013). Abnormalities of storage (obtained during the cystometrogram portion), voiding (obtained during the pressure flow portion), and postmicturition may be ascertained during the study. Although it is the goal of each urodynamic study to recreate the symptoms reported by the patient, it is clear that this is not always feasible. For example, patients with symptoms of pure stress incontinence often have divergent urodynamic findings; it then becomes the role of the clinician to determine if the urodynamic observations or the patient-reported symptoms are more appropriate to treat (Digesu et al., 2009).

Terminology of Lower Urinary Tract Symptoms and Incontinence

The terminology used to describe LUT dysfunction in women has been standardized through a joint effort of the International Continence Society (ICS) and The International Urogynecological Association (IUGA) (Table 115.1; Haylen et al., 2010). Although LUTS are the focus of the present chapter, this important document and its precedent manuscript (Abrams et al., 2002) also include standard terminology used for characterizing prolapse, as well as for performing and interpreting urodynamic investigations. LUTS terminology is typically broken down into symptoms associated with (1) incontinence, (2) bladder storage, (3) bladder sensation, (4) voiding, and (5) postmicturition disturbances.

TABLE 115.1

Lower Urinary Tract Symptom Definitions

SYMPTOM	DESCRIPTION
Stress urinary incontinence	Complaint of involuntary urinary loss with physical exertion, sneezing/coughing, or other activities raising intra-abdominal pressure
Urgency urinary incontinence	Complaint of involuntary urinary loss associated with sensation of urgency
Mixed urinary incontinence	Complaint of involuntary urinary loss associated with physical exertion/rise in intra-abdominal pressure *and* with urgency
Nocturnal enuresis	Complaint of involuntary urine loss during sleep
Continuous urinary incontinence	Complaint of continuous urine loss, day and night
Insensible urinary incontinence	Complaint of urine loss without knowledge of what precipitated the event or when it occurred
Urinary frequency	Complaint that micturition occurs more frequently than deemed normal
Urinary urgency	Complaint of sudden compelling desire to urinate that is difficult to defer
Overactive	Complaint of urinary urgency, with or without urgency incontinence,

bladder syndrome	typically with frequency and nocturia
Nocturia	Complaint of interruption of sleep resulting from the need to void, where the interruption is preceded and followed by sleep

Incontinence

UI is the symptomatic complaint of the involuntary loss of urine. For UI assessment, it is essential to establish the causative factors (i.e., urgency, particular activity or action), severity, impact on QoL, duration, and frequency with which the incontinence occurs. Validated questionnaires, bladder diaries, physical examination, and urodynamic testing may be helpful to evaluate UI symptoms and to distinguish the type of incontinence present. None of these tools alone is capable of answering all of these essential questions regarding UI, and their combined use is often helpful in developing treatment strategies.

Stress urinary incontinence (SUI) is the complaint of involuntary loss of urine with physical exertion (i.e., walking, straining, exercise) or other activities that cause a rise in intra-abdominal pressure (such as sneezing or coughing). It can be witnessed on exam as involuntary leakage per urethra synchronous with effort, straining (Valsalva maneuver), physical exertion, or coughing. This provocative testing is often performed during an office supine stress test. **Urodynamic stress incontinence refers to the finding of involuntary urine leakage during filling cystometry associated with an increase in intra-abdominal pressure in the absence of a detrusor contraction.**

Urgency urinary incontinence (UUI) is the complaint of involuntary urine loss associated with urgency. It can, occasionally, be noted on physical exam as the observation of involuntary leakage from the urethra synchronous with the sensation of a sudden, compelling desire to void that is difficult to defer. Whereas urgency incontinence may be diagnosed urodynamically (leakage associated with sudden urgency during bladder filling, not associated with increase in abdominal pressure measurement), it need not be present with any specific urodynamic finding such as detrusor overactivity (DO), bladder oversensitivity, or diminished maximum bladder capacity. **Detrusor overactivity incontinence, a urodynamic diagnosis, may be present in patients with UUI, although it need not be present to establish the diagnosis**

of UUI.

Mixed urinary incontinence (MUI) is the complaint of involuntary urine loss associated with urgency and also associated with effort, physical exertion, sneezing, or coughing, or other activity causing a rise in intra-abdominal pressure. Mixed symptoms may be urge predominant, stress predominant, or equal. **Postural UI is the complaint of involuntary urine loss associated with a change in position (typically from sitting/lying down to standing). Nocturnal enuresis is the complaint of involuntary urine loss occurring during sleep** and should be distinguished from urgency incontinence, which may occur during the night after being awakened to void but having insufficient time to get to the bathroom to void. **Continuous UI is the complaint of continuous urine loss, day and night,** typically seen with fistula of the lower urinary tract involving the vagina (i.e., vesicovaginal and ureterovaginal fistulae). Patients with continuous incontinence may have few or no volitional voids. **Insensible UI is the complaint of urine loss when the patient is unaware of how or precisely when the urine loss occurred.** Coital incontinence is the complaint of involuntary loss of urine with sexual intercourse. It may occur with initial penetration, intromission, and/or during orgasm.

Bladder Storage and Sensation

These symptoms are associated with abnormalities of bladder filling and include increased daytime **frequency,** which is the complaint that micturition occurs more frequently than previously deemed normal. In general, eight or more voids within a 24-hour period are considered more than normal, although this finding alone does not necessarily imply bladder dysfunction because polyuria will normally result in an increase in urinary frequency. **Nocturia is the complaint of interruption of sleep because of the need to void, where each interruption is preceded and followed by sleep**. **Urgency is the sudden compelling desire to urinate, which is difficult to defer.** Urge, by comparison, is a normal bladder sensation that occurs and signals the need to micturate. **OAB syndrome includes urinary urgency, with or without urgency incontinence, typically accompanied by frequency and nocturia.**

Increased bladder sensation implies that the patient experiences the desire to void earlier than previously deemed normal. This differs from urgency in that voiding can be postponed. Such patients may report a sensation of the need to void with less than 50 mL of bladder filling during urodynamics. **Reduced bladder sensation,** in contrast, implies that the desire to void comes later than that previously experienced by the patient, despite the fact that the patient is aware that the bladder is filling. **Absent bladder sensation** involves the complaint that the sensation of bladder filling and the desire to void are absent.

Epidemiology of Urinary Incontinence in Women

General Comments

Epidemiologic studies on the topic of UI must be closely scrutinized when determining their relevance. Several factors must be considered when evaluating these types of data. Among the most important of these factors is the definition of UI—indeed altering the definition will result in widely divergent estimates of disease prevalence. In a condition that often does not rely on a specific pathological diagnosis, and one in which the diagnosis may often be made, appropriately, by history alone, estimates clearly vary widely. The importance of clearly defining the patient population and surveying instrument has been highlighted in a recent study. This study suggested that studies that do not specifically focus on women with UI using validated questionnaires that permit adequate grading of symptom severity may give the most accurate prevalence information (Bedretdinova et al., 2016).

Questionnaires to assess incontinence differ greatly in specificity, length, and complexity, which often results in very different estimates of prevalence. **Questionnaires used to characterize incontinence attempt to differentiate the type of incontinence present, identify the frequency with which UI occurs, and assess the severity of the condition as determined by bother or impact on QoL.** The timeframe questioned in the survey instrument must be determined, which will affect the prevalence rates greatly. Thus, for example, asking a woman if she has leaked (at any time) in the past month will result in very different findings than if the timeframe is narrower**. In addition, a questionnaire that inquires about bother associated with leakage to define UI will yield varying findings from a questionnaire that merely assesses the presence of the condition**. In a nonmorbid condition such as UI, the impact of the condition on QoL (associated bother) would seem to be paramount. Similarly, studies that rely on the physical demonstration of UI, either on exam or during urodynamics, are likely to report very different findings regarding condition prevalence than those based on questionnaires alone. An assessment of UI prevalence must include careful analysis of the incontinence definition used.

Patient populations may also be different in assessment of epidemiologic aspects of UI. Examining a group of young, nulliparous women, for example, will yield different findings than examining octogenarians living in skilled nursing facilities. Studies examining incidence and remission rates of UI may be even more vulnerable to bias and misinterpretation given the high overall prevalence of this condition compared with the relatively low incidence rate. Time between inquiries regarding incontinence, age of the population studied, duration of time that the patient is queried regarding the last time she experienced leakage, and the nature of the questions asked will often differ considerably among studies. All of these issues must be considered when evaluating reported incidence rates.

For young women, pregnancy, which is further discussed in the risk factors section, may be the most common event associated with incident incontinence, and the risk increases with gestational age. Risk factors for the development of SUI during pregnancy have been analyzed (Sangsawang, 2014). Obesity, pre-existent SUI, gestational diabetes, age, and constipation have been noted to increase the risk of SUI during pregnancy. Also, compared with age-matched nulliparous women, primiparous women appear to have a threefold increased likelihood of UI during pregnancy that remains 2.5 times higher 1 year after delivery (Hansen et al., 2012). Furthermore, more than 50% of affected women reported a significant impact on QoL (Dolan et al., 2004). A recent analysis that followed women for 12 years after pregnancy evaluated incidence and remission rates of UI after delivery (MacArthur et al., 2016). Overall, 33% of women reported UI at 3 months after their delivery. Interestingly, only 13.5% of women who reported UI at 3 months after delivery had no UI at 6 and 12 years. Of those women reporting at all time points who had UI at 3 months, 64% reported it again at 6 and 12 years. **These data highlight that incident UI is relatively common after pregnancy (33%–40%) and that remission rates are surprisingly low, depending on the UI definition used.**

Several factors have been noted to decrease the risk of UI during and after pregnancy. Properly performed pelvic floor muscle training programs during and after delivery may reduce the risk of incident UI during pregnancy as well as post-delivery UI (Ahlund et al., 2013; Boyle et al., 2008; Stafne et al., 2012). In addition, weight-reduction programs after delivery have been shown to hasten the recovery from UI after delivery (Wesnes, 2010).

Hysterectomy may also be associated with incident incontinence, as well as resolution of pre-existing UI in some patients. A study of more than 25,000 women enrolled in the National Swedish Registry for Gynecologic Surgery noted that, of the 70% of women without UI before hysterectomy, 8.5% developed de novo UI (Bohlin et al., 2017). Obesity and prior vaginal delivery were associated with incident UI after hysterectomy. Interestingly, 13% of patients who had UI before hysterectomy did not report it 1 year after surgery. Larger uterine weight (>300 g), low body mass index (BMI) (<25 kg/m^2), and presence of POP were predictive of UI resolution.

Overall, in middle-aged women (40 to 60 years), annual UI incidence rates appear to range from 1% to 10%, approximately 3% for each category of UI each year (Komesu et al., 2016). One extended study following 40-year-old women for 10 years showed that 40% developed new-onset incontinence during this period (Jahanlu and Hunskaar, 2011). As one would expect, SUI is most commonly reported among younger cohorts reporting new symptoms (responsible for 50% of new cases). Interestingly, the incidence of SUI, but not UUI or severe UI, was noted to increase with the menopausal transition from ages 48 to 54 (Mishra et al., 2010). In general, older cohorts have been found to have higher annualized incidence rates—typically between 10% and 20% (Herzog and Fultz, 1990). Among middle-aged or older women, Caucasians, compared with African-Americans, appear more likely to develop UI when followed over 5 years (Thom et al., 2010). Caucasian women with higher BMI at baseline and those with weight gain during the survey period appeared to be at greatest risk.

Annualized resolution rates typically remain less than 10%, although UI remission is clearly and consistently noted in most longitudinal studies. Higher remission rates have been noted in several studies and may be more typical of studies following younger patients at baseline (Botlero et al., 2011) and those with less severe forms of UI (Espuna-Pons et al., 2017). Remission rates as high as 30% have been noted when studying patients for prolonged periods of time (biannual surveys), with MUI having the lowest likelihood of resolving (Komesu et al., 2016). Interestingly, remission rates may be highest among African-American women (Townsend et al., 2011), although other studies have noted remission rates for SUI highest among Hispanic women (Komesu et al., 2016). The fact that remission has been reported emphasizes the existence of transient causes of incontinence, the subjective nature of the condition, and the possibility of recall bias.

Key Points: Incidence and Remission of Urinary

Incontinence

- Pregnancy/delivery is associated with incident incontinence in up to 33% of patients, and remission may be as low as 13% for up to 12 years.
- Hysterectomy may be associated with incontinence resolution in 13% of patients and is more common when the uterine weight is more than 300 g.
- Annualized incidence rates for UI in women vary between 1% and 10% (approximately 3% for each subtype) and are heavily influenced by the population surveyed and the survey tool used.
- The remission rate for UI is variable depending on the definition used and population studied. Remission appears to be higher in younger women and is lower overall for MUI.
- Remission rates for men with UI are considerably higher than for women in most studies.

Risk Factors for Urinary Incontinence in Women

Aging

Aging has clearly and consistently been identified as an independent risk factor for the development of UI in women (Fig. 115.1). This risk extends beyond the menopausal years, when many epidemiologic studies demonstrate a sharp rise in incidence. In a study of more than 5000 Medicare beneficiaries (all more than 65 years of age), 37% reported UI (Hawkins et al., 2011). There was a clear association with aging noted, even among this older group. Another survey of nearly 800 community-dwelling women aged more than 65 years showed that 28% of women reported UUI occasionally or often, whereas 21% reported a similar degree of SUI (Sims et al., 2011). A systematic global review of urgency urinary incontinence noted a very clear association between age and UUI in men and women (Fig. 115.3; Milsom et al., 2014). **These findings highlight the change in incontinence type that tends to occur with aging, with a shift away from SUI toward MUI and UUI.** Interestingly, among older women (>75) UUI appears to be associated with impaired physical mobility, whereas SUI is not (Fritel et al., 2013). Among nonagenarians, UI has been independently linked to frailty and has been established as an independent risk factor for death, suggesting that treatment may be warranted even among the oldest of our patients (Berardelli et al., 2013).

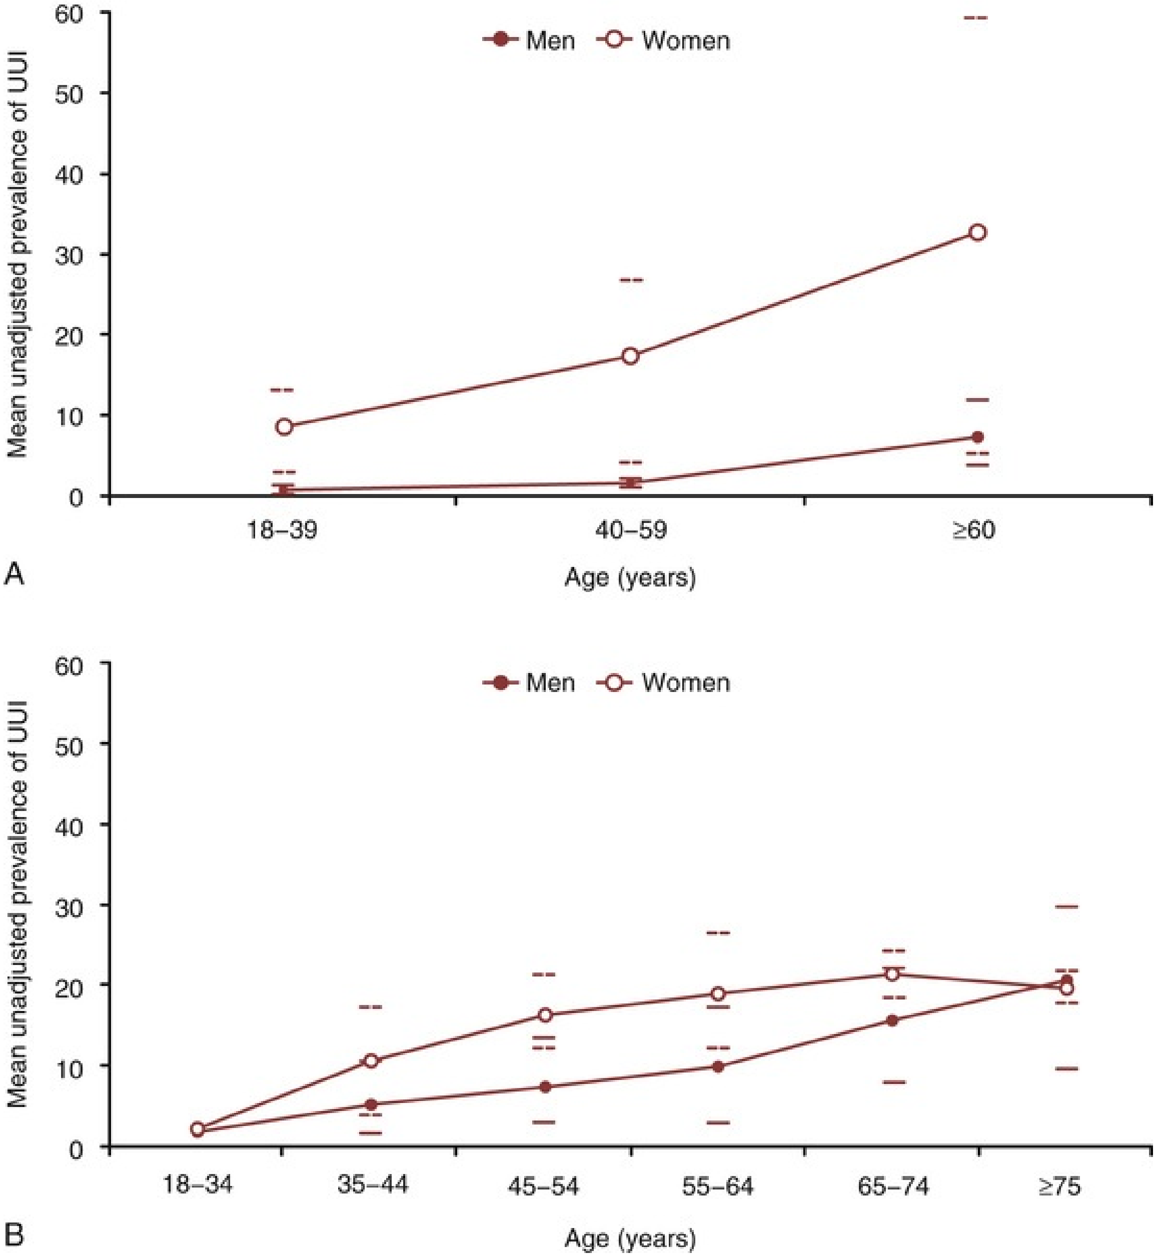

FIG. 115.3 Prevalence estimates of urgency urinary incontinence (UUI) (including UUI and mixed urinary incontinency [MUI]) in men compared with women, compared by age. Panel A uses a wider age interval (20 years). Panel B (based on different studies) summarizes data from studies

reporting a narrower age interval and demonstrates the increasing incidence of UUI in aging men, which in some series exceeds the prevalence seen in women. *Solid bars* (men) and *dashed bars* (women) indicate maximal and minimal values reported in the studies included. (From Milsom I, Coyne K, Nicholson, et al.: Global prevalence and economic burden of urgency urinary incontinence: a systematic review. *Eur Urol* 65:79–85, 2014.)

Women living in long-term care facilities (LTCFs) may be at the greatest risk for UI. Several studies have demonstrated the high prevalence of UI in women living in LTCFs (Hunskaar et al., 1998; Ouslander et al., 1982; Saxer et al., 2008; Sgadari et al., 1997). An analysis of nearly 5000 women living in residential care facilities found an incontinence prevalence of more than 40% at admission (De Gagne et al., 2013). Severe impairment in the activities of daily living had the strongest association with the presence of UI (odds ratio [OR] 21.59). Poor nutritional status, impaired mobility, and increased dementia symptoms have been correlated with the severity of UI. Group-based behavioral exercise programs have been shown to decrease incontinence in women in LTCFs (Tak et al., 2012).

Pregnancy

Pregnancy increases the risk of future incontinence. As noted previously, the risk of incident incontinence may be as high as 40%, and risk factors have been described. **It is also clear that the development of UI during pregnancy does increase the risk of future (and persistent) incontinence.** In the large Swedish Registry study, of those women reporting at all time points who had UI at 3 months, 64% reported it again at 6 and 12 years (MacArthur et al., 2016). Older age at time of pregnancy and obesity appear to be associated with persistent incontinence after pregnancy. Similarly, a systematic review of risk factors for UI noted that age over 30 at the time of first pregnancy increases the likelihood of UI later in life (OR 3.1) (Troko et al., 2016). Other studies have noted that alcohol consumption and depression were associated with persistent incontinence after pregnancy, whereas higher level of physical activity and black race were protective (Maserejian et al., 2014).

Aspects of Delivery

Not only does pregnancy confer an increased risk of UI but also mode, duration, and nature of the delivery also appear to influence the risk of UI later in life.

Cesarean delivery appears to confer an advantage over normal spontaneous vaginal delivery with regard to the development of UI and SUI (Findik et al., 2012). Five years after delivery, primiparous women who had undergone cesarean section were significantly less likely to report UI overall, although these women may be more bothered by UUI when it occurs than their counterparts (Liang et al., 2013). Similarly a study of women followed for 12 years after delivery noted that, although cesarean section did confer a decreased likelihood of UI, this was only the case if all deliveries were by this method—if other deliveries were vaginal, any protective effect was lost (MacArthur et al., 2011). **Further, it has been suggested that the number needed to treat to prevent one case of moderate to severe urinary incontinence is 13 cesarean sections** (Gyhagen et al., 2013a and 2013b). Other factors such as length of delivery, use of forceps, type of anesthesia, and use of episiotomy have been suggested as factors potentially associated with the development of either transient or long-standing UI after delivery, although no conclusive evidence supports modifying obstetric practice based on these findings. In contrast, **any history of vaginal birth of a large baby with increased birth weight has been consistently associated with an increased likelihood for developing UI** (Connolly et al., 2007; Thom et al., 2011). For example, among women who had at least one child with a birth weight of more than 4 kg, the OR of experiencing weekly UI later in life was 1.47 when compared with those without large babies.

Parity

A single pregnancy and delivery significantly increase a woman's risk for UI in later life, with an OR of approximately 1.5. Subsequent deliveries may increase this risk further, although a direct linear relationship is unlikely (Danforth et al., 2006; Grodstein et al., 2003; Juliato et al., 2017; Rortveit et al., 2001; Waetjen et al., 2007). Whether the number of deliveries is clearly associated with UI risk is unclear: a survey of more than 8000 women in Germany and Denmark demonstrated equivalent elevated risk (OR approximately 1.5 compared with nulliparous women) regardless of the number of deliveries (Pedersen et al., 2017). This risk appears to be accentuated by the timing of the first birth; women having their first child closer to the age of 20 seem to be at greatest risk in most studies, although controversy exists on this topic. The association between incontinence and parity appears to be strongest for SUI.

Race and Ethnicity

Most cross-sectional studies have indicated that Caucasian women have an increased prevalence of UI and an increased risk for developing incident UI/SUI when compared with African-American women and Asian women (Townsend et al., 2010). Although various explanations exist for this finding, at least one group has noted higher urethral closure pressures in African-American women (DeLancey et al., 2010). This difference in prevalence is less clear when compared with other populations, including Hispanic women. Differences in MUI and UUI based on race are less obvious in comparison and, in fact, are likely inconsequential overall. It appears that Caucasian and African-American women are equally likely to seek care for UI (Berger et al., 2011), although this difference is clearly affected by the degree of leakage (Lewicky-Gaupp et al., 2009). Cross-cultural differences in UI prevalence are less clear overall. However, after including only studies reporting similar definitions for UUI, a systematic review noted substantial differences in UUI prevalence in different countries ranging from as low as 0.51% in Nigeria to as high as 14.3% in Germany (Milsom et al., 2014) (Fig. 115.3).

Hormonal Therapy

Oral estrogen treatment with or without progestogens is associated with the development of UI in middle-aged and older women (Brown et al., 2009). When compared with placebo, the rate of incident incontinence nearly doubled during a 1-year period in a well-conducted large clinical trial of postmenopausal women treated with placebo, estrogen, or estrogen and progestin therapy (Hendrix et al., 2005). By comparison, topical (vaginal) estrogen use is not clearly linked to the development of SUI and has proven efficacy in treating women with vaginal atrophy and recurrent urinary tract infections (UTIs).

Obesity

The presence and severity of UI are strongly associated with obesity in women. Although the association appears to be strongest for SUI and MUI, all types of UI have been associated with the development of obesity in women. BMI in excess of 30 has been shown to more than double a woman's risk of UI (Danforth et al., 2006; Hannestad et al., 2003). Even women who do not meet the criteria for obesity but who are overweight (BMI >24) are at increased risk for UI, suggesting a progressive impact of weight gain on urinary continence mechanisms (Troko et al., 2016). Incontinence associated with weight gain may be reversible, however, because surgically induced weight loss and weight loss experienced as a result of a carefully executed weight-loss program have been associated with improvements in UI symptoms that are maintained as long as the weight is kept off (Bump et al., 1992; Richter et al., 2005). A meta-analysis of nonsurgical weight-loss programs (diet, exercise, medications) noted significant improvements in UI with a mean standardized reduction of −0.30 episodes per day (Vissers et al., 2014).

Smoking

Although data remain inconsistent, several compelling studies have demonstrated a link between urinary symptoms and smoking. A Finnish study of more than 2000 women noted a clear association between symptoms of urinary urgency and frequency and current smoking status. In fact, heavy smoking was associated with more severe urgency symptoms than light smoking (Tahtinen et al., 2011). In a cross-sectional study of more than 80,000 nurses, severe incontinence was associated with current smoking (OR 1.34) (Danforth et al., 2006). Last, among women scheduled for SUI surgery, incontinence severity was clearly correlated with current tobacco use. Overall, current smokers had 56% more incontinence episodes than nonsmokers (Richter et al., 2005). Various causes for this link have been suggested, and although some data question the relationship between smoking and incontinence, there appears to be a growing consensus that some relationship exists, particularly with storage urinary symptoms.

Diet

Certain foods have been purported to be associated with UI. Overall data are inconsistent, with the association between caffeine (coffee in particular) intake and symptoms of urgency incontinence, mixed incontinence, or OAB generating the most compelling data. This appears to be true in men and women (Davis et al., 2013). There is no consistent link between dietary intake and SUI in most studies. Carbonated beverages and artificial sweeteners have also been primarily associated with urgency symptoms, although confirmatory studies are lacking (Jura et al., 2011).

Medical Conditions

UI appears to be more prevalent among women with certain medical conditions, including diabetes mellitus (DM) and depression. The prevalence of UI among women with type 2 diabetes may be as high as two times greater than age-matched nondiabetic women, with emerging evidence suggesting the same finding in women with type 1 DM (Lifford et al., 2005; Phelan et al., 2009a). Among more than 9000 nurses with type 2 DM who were surveyed, 48% reported at least monthly UI, with 29% reporting at least weekly incontinence episodes. Obesity enhanced the risk of UI significantly in this cohort of women (Devore et al., 2012). Similar findings were noted in an interventional trial (weight loss) of obese women with type 2 DM, in whom 27% reported weekly incontinence (Phelan et al., 2009b). The National Health and Nutrition Examination Survey (NHANES) cross-sectional study of 1400 women with type 2 DM additionally identified macroalbuminuria and peripheral neuropathic pain as independent risk factors for UI in patients with type 2 diabetes (Brown et al., 2006). Data from women with type 1 DM are less robust, although a study of more than 500 women demonstrated weekly incontinence in 17% of them, which was a far greater rate in comparison with a nondiabetic cohort from the NHANES analysis (Sarma et al., 2009).

Depression has also been associated with UI in women. The link is likely multifactorial; certainly UI leads to a diminished perception of one's self-health, but a common pathophysiologic link between depression and UI has also been proposed. **Regardless of the direction of the association, it is clear that the presence of depression leads to an increased likelihood of the later development of UI in women** (Thom et al., 1997).

The presence of multiple comorbid conditions has also been associated with UI (Melville et al., 2005). In addition to depression and diabetes, the presence of hypertension and osteoarthritis has been independently associated with UI (Renata et al., 2016). Although the mechanism for these individual associations likely differs, the cumulative effect of multiple conditions may result in UI in vulnerable women.

Key Points: Risk Factors for Urinary Incontinence in Women

- **Age:** Aging is the strongest nonmodifiable risk factor for the development of UI in women. Advancing age is clearly linked with a greater likelihood of incontinence and a shift away from SUI to, more commonly, MUI or UUI in later years.
- **LTCFs/impairment in activities of daily living:** Distinct from aging, maintaining residence in an LTCF is an independent risk factor for UI. Similarly, severe impairment in activities of daily living has a particularly strong association with UI.
- **Pregnancy and postpartum:** Prevalence of SUI, in particular, increases during pregnancy and increases with gestational age during pregnancy. Prevalence decreases considerably within 3 months postpartum. Properly performed pelvic floor muscle training has been shown to decrease the likelihood of developing SUI.
- **Aspects of delivery:** Cesarean section, when compared with vaginal delivery, appears to confer an advantage with regard to the later development of UI. This advantage may be lost with even one vaginal delivery. Birth weight of the largest child also appears to be positively correlated with an increased risk of later UI. Other factors such as forceps use and length of delivery have been proposed as risk factors for UI, although overall the association is less clear.
- **Parity:** Whereas a single vaginal delivery increases the risk of UI (and SUI in particular), subsequent deliveries further increase this risk. Age at time of delivery also appears to augment this risk, and those women who are younger when they first experience pregnancy and delivery appear to be at greatest risk.
- **Race/ethnicity:** An increased prevalence of UI and SUI is noted in Caucasian women when compared with African-American and Asian women. Differences compared with Hispanic populations are less clear.
- **Hormonal therapy:** Oral estrogen use with or without progestogen is associated with the development of SUI in middle-aged and older women. Topical estrogen has not been clearly associated with this finding, and it can be used for the treatment of vaginal atrophy and, frequently, associated UTIs.
- **Obesity:** The presence and severity of UI is positively correlated with obesity and weight gain. SUI and MUI are most strongly linked to BMI. UI related to weight gain may be reversible, with either surgical treatment or

regimented weight-loss programs providing evidence of substantial improvements in UI.

- **Smoking:** Urinary urgency and frequency are associated with active smoking, although a link with UI is less clear. Heavy smokers may be at greatest risk. Data on the impact of smoking cessation are scant.
- **Diet:** Caffeine intake (coffee in particular) has been linked to OAB. No clear association exists with SUI. Carbonated beverages and artificial sweeteners have also been associated with storage urinary symptoms, although less clearly so.
- **Medical conditions:** Diabetes and depression are the two most common medical conditions associated with UI, though multi-morbidity in general is associated with UI. Depression in the early years or midlife increases the risk of developing UI later in life.

Epidemiology of Urinary Incontinence in Men

Prevalence, Incidence, Remission Rates

The overall prevalence of UI in men is considerably lower than that found in women. In particular, SUI is uncommon in men, with the exception of men who have previously undergone radical pelvic surgery (e.g., radical prostatectomy [RP] or abdominoperineal resection) or endoscopic or open surgery for benign prostatic enlargement or who have a neurologic condition that may predispose them to SUI. UUI and MUI are more common in men than SUI, and in many cases these conditions may be attributable to BOO from benign prostatic enlargement, other outlet disorders, OAB, or other inflammatory or infectious processes. **Prevalence estimates for UI in men have ranged from 11% to 34% in older men, with up to 11% reporting daily incontinence** (Buckley et al., 2010; Coyne et al., 2012; Markland et al., 2010).

The likelihood of developing UI in men is age dependent. Several studies have indicated an incidence rate of approximately 1% to 10% annually in men from 60 to 70 years of age followed for 5 to 10 years (Herzog and Fultz, 1990). The remission rate for UI tends to be higher in men than in women. This is largely because of the fact that leakage in men is more typically urgency related, which may have several reversible (infectious/inflammatory) causes. **Depending on the age studied, remission rates as high as 40% have been noted in men with UI** (McGrother et al., 2004).

Risk Factors for Urinary Incontinence in Men

Age appears to be the strongest independent risk factor for UI developing in men, an association that may be even stronger than that noted in women (Diokno et al., 2007). Men appear to be particularly vulnerable to UI with infectious processes such as acute cystitis and prostatitis, the prevalence of which are also clearly associated with aging. Similar to findings in women, altered cognition, diminished mobility, and the presence of other comorbidities are associated with an increased likelihood of UI. Certain neurologic conditions more commonly found in aging populations (Parkinson disease, cerebrovascular accident [CVA]) are also associated with incontinence in men, most commonly UUI. Recent data suggest an association between UI and chronic obstructive pulmonary disease (COPD) in men (Burge et al., 2017). One study noted an interesting association between American men younger than 55 and UI; these men were 3 times more likely to report UI (Vaughan et al., 2014).

RP and other radical pelvic surgeries have been associated with the development of UI in men. The likelihood of UI varies considerably, with overall estimates ranging from 8% to 60% at 1 year after RP depending largely on the definition of UI used (Ficarra et al., 2009). **The absence of preexisting LUTS/previous transurethral resection of the prostate (TURP), technique of surgery (bladder neck sparing and neurovascular bundle sparing), and younger age at the time of surgery have been shown to be associated with a lower risk of postoperative UI,** although conflicting data exist (Gupta et al., 2011). **The impact of robotic-assisted approaches to RP on UI rates has been modest, with the most recent studies noting incontinence rates comparable with the open approach** (Haglind et al., 2015). When compared with a laparoscopic approach, robot-assisted RP appears to result in earlier return to continence and overall improved continence (95% vs. 83% at 1 year) (Porpligia et al., 2013). In comparison, TURP, whether performed with electrosurgical cauterization or using the potassium titanyl phosphate (KTP) laser approach, is associated with a low (1%) likelihood of developing UI postoperatively.

Key Points: Epidemiologic Aspects of Urinary Incontinence in Men

- UI is considerably less prevalent in men than in women.
- UUI is the most common form of UI in men, followed by MUI and then SUI. In some studies of elderly men, UUI rates exceed that reported in women.
- SUI in men is associated with previous radical pelvic surgery (in particular RP) and certain neurologic diseases.
- SUI prevalence rates following RP range from 8% to 60%.
- Robotic prostatectomy may lead to an earlier return of continence compared with laparoscopic approaches, but there is no clear consensus that the robotic approach has led to a lower incidence of postoperative UI compared

with an open approach.

- Remission rates for UI are higher in men than in women. Remission rates as high as 40% have been reported.
- Age is even more closely associated with the development of UI in men than in women.

Definitions and Classification of Pelvic Organ Prolapse

Pelvic organ prolapse refers to the downward displacement of the pelvic organs, which results in protrusion of the uterus and/or the different vaginal compartments and their surrounding organs, such as the bladder, the rectum, or the bowel. It results from the loss of support of one or more compartments of the vagina. Prolapse should be described using segments of the lower reproductive tract. Older terms such as cystocele, rectocele, enterocele, or urethrovesical junction prolapse should be avoided because of the uncertainty of the anatomic structure on the other side of the vaginal bulge, especially in women who had previous prolapse surgeries. **Anterior compartment prolapse** corresponds to the descent of the anterior vaginal wall. Most commonly this represents the descent of the bladder (**cystocele**), but it can also represent an anterior enterocele, especially after prior reconstructive surgery. It is the most common segment of the vagina to prolapse (Hendrix et al., 2002). **Apical prolapse** corresponds to the descent of the uterus (uterine or cervical prolapse) or, in a post-hysterectomy patient, the vaginal cuff. It can include the small intestine **(enterocele).** An enterocele is present when a peritoneal sac containing part of the bowel and possibly the omentum comes down in the area of the rectovaginal space. It can be asymptomatic but can also be associated with significant defecatory dysfunction and pelvic pain or pressure (Takahashi et al., 2006). **Posterior compartment prolapse** is a weakness of the posterior vaginal wall and can involve the rectum **(rectocele)** but can also include the small bowel or colon even in the presence of an intact uterus. **Procidentia** refers to total vaginal eversion with complete uterine or vaginal cuff prolapse.

Symptoms of Pelvic Organ Prolapse

Prolapse can cause a multitude of symptoms and have a significant impact on a woman's quality of life**. A vaginal bulge that can be seen or felt by a patient is the most specific symptom for POP** (Tan et al., 2005). Other symptoms that can be attributed to POP include pelvic pressure or discomfort, discharge, splinting or digitation for urination or defecation, and low backache. Even though it is important to assess urinary symptoms such as frequency, nocturia, urinary and fecal incontinence, voiding and defecatory dysfunction, and sensation of incomplete emptying in patients with prolapse, **there is a poor correlation between these symptoms and the severity and site of prolapse** (Ellerkmann et al., 2001). In fact, many of those prolapse-related symptoms are not caused by the prolapsing vagina but by coexisting or associated bladder, anorectal, or pelvic floor dysfunction. This is especially true for many bowel symptoms such as constipation, fecal incontinence, feeling of incomplete emptying, straining, and defecatory dysfunction. In general, at the most, weak correlations have been noted between bowel symptoms and the presence and severity of pelvic organ prolapse (Ellerkmann et al., 2001). Clinically, this lack of correlation has significant relevance. For example, **the presence of constipation alone without the sensation of a vaginal bulge should rarely prompt surgical intervention for posterior compartment prolapse**. The exception to this would be if the patient feels that stool gets caught “in a pocket” during defecation and needs to splint to have a bowel movement. This particular symptom can be a sign of rectocele defect. However, there seems a much stronger correlation between the development of symptoms such as sensation of vaginal bulge or need to splint to urinate or defecate when the leading edge of the prolapse is beyond the vaginal hymen (Swift et al., 2003).

Other symptoms and signs should also be assessed in patients with POP. For example, the timing of the development of SUI is important to determine. In general, the severity and prevalence of SUI declines as the POP extends beyond the hymen, possibly from urethral obstruction secondary to urethral kinking, and treatment of POP with concomitant treatment for SUI may be indicated in certain cases (Ellerkmann et al., 2001; Wei et al., 2012). Sexual dysfunction should also be evaluated because POP is known to negatively affect body image and sexual function, and treatment can improve sexual function (Jelovsek and Barber, 2006; Özel et al., 2005). Sexually inactive patients should be asked about their desire to resume sexual activity after POP repair because this can influence treatment decisions. A history of abnormal or postmenopausal uterine bleeding should never be attributed to POP and warrants appropriate gynecologic evaluation before any intervention for POP. Although many patients complain of low back pain and pelvic pain secondary to their prolapse, there has been little evidence indicating that prolapse can cause pain. The complaint of pain with prolapse warrants investigation of other sources of pain before attributing it to prolapse. A trial of pessary can be very useful to determine if some of the patient's symptoms are a result of prolapse. If the symptoms improve with a pessary, it can be assumed that POP is likely the cause of these symptoms, and they are more likely to improve after surgical management.

Physical Examination of Pelvic Organ Prolapse

Multiple grading systems have been used to classify the degree of anatomic deformity. One of the most commonly used is the **Baden-Walker Halfway Scoring System.** This system uses the hymen as a fixed anatomic reference point. A score is assigned to each of the six specific midline sites (urethral, vesical, uterine, cul de sac, rectal, and perineal). A score is assigned to each of the six specific midline sites (urethral, vesical, uterine, cul de sac, rectal, and perineal). It consists of four grades. Grade 0 is considered normal, absence of prolapse. Grade 1 is a descent halfway to the hymen, grade 2 is a descent to the hymen, grade 3 is a descent halfway past the hymen, and grade 4 represents maximum prolapse. Although this system offers a good description of the prolapse, there is a lack of information about the exact location of specific structures, and the interobserver variability is high (Persu et al., 2011).

In an effort to design an objective and reproducible system of grading prolapse, the **Pelvic Organ Prolapse Quantification (POPQ) system** (▶Video 115.1) was developed in 1993 (Bump et al., 1996). This system was later updated in 2002 (Abrams et al., 2002). It is now the recommended staging system for prolapse (Haylen et al., 2016). The POPQ system relies on specific measurements of defined points in the midline of the vaginal wall. All these points are measured in relation to a fixed reference point, which is the hymenal ring. The use of this scoring system should be favored for research purposes, as well as routine clinical use, because the measurements are much more precise and the interobserver agreement and reliability are also improved (Swift et al., 2006).

The POPQ system provides a precise, objective description of a woman's pelvic support that defines POP relative to a fixed reference point, the hymen. There are three reference points located anteriorly **(Aa, Ba, C)** and three located posteriorly **(Ap, Bp, and D).** In addition, there are three other landmarks **(gh, pb, and tvl).** All points are measured in centimeters. Negative numbers refer to points located inside the introitus, and positive numbers reflect prolapse beyond the introitus, with the plane of the hymen being defined as zero (Fig. 115.4). The Aa point is located 3 cm proximal to the hymenal ring on the anterior vaginal wall and corresponds to the approximate location of the urethrovesical junction. By definition, the range of position of point Aa relative to the hymen is −3 and +3, −3 being in the absence of prolapse. The Ba is the most distal point of the prolapse between the Aa point and the vaginal apex. In the absence of prolapse, its position is −3. In woman with total uterine prolapse or posterior hysterectomy vaginal eversion, Ba would have a positive value equal to the position of the vaginal cuff (point C). The C point represents the most distal edge of the cervix or the leading edge of the vaginal cuff (if patient has had prior hysterectomy). The D point denotes the posterior fornix or pouch of Douglas in a woman who still has a cervix. It represents the level of uterosacral ligament attachment to the proximal posterior cervix. The D point is omitted in the absence of cervix. On the posterior vaginal wall, two other points are measured, Ap (point located 3 cm proximal to the hymen, which is meant to parallel the Aa point on the anterior vaginal wall) and Bp (lowest point of the prolapse between the Ap and the apex). In the same way as for point Ba, Bp has a value of −3 in the absence of prolapse and would have a positive value equal to the position of the vaginal cuff in woman with total uterine prolapse or posterior hysterectomy vaginal eversion. All of these measurements are taken during demonstration of maximal prolapse (with the patient either straining/performing Valsalva maneuver, either supine or standing). The last three measurements are taken at rest. The genital hiatus (gh) is the distance between the middle of the urethral meatus and the posterior hymenal ring. The perineal body (pb) is the distance between the posterior aspect of the genital hiatus to the midanal opening. Last, the total vaginal length (tvl) at rest is the length of the vagina (cm) from the posterior fornix to the hymen when point C or D is reduced to its full normal position. Measurements directly after the removal of a vaginal pessary are unreliable because it will tend to underestimate the degree of prolapse.

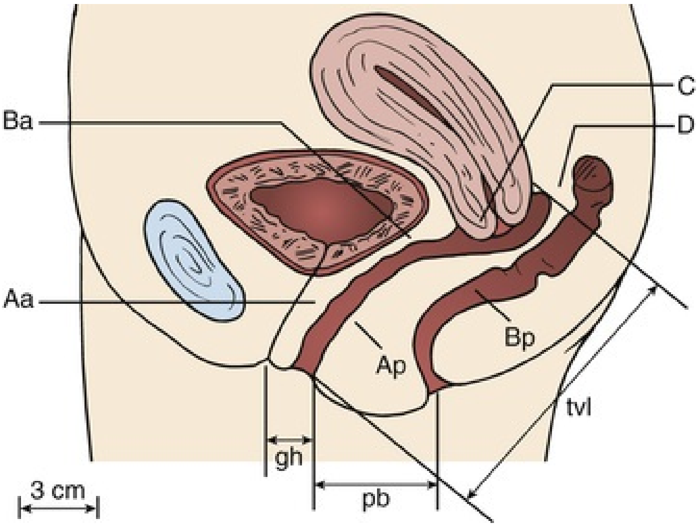

FIG. 115.4 Pelvic Organ Prolapse Quantification system and specific points measured. *gh,* Genital hiatus; *pb,* perineal body; *tvl,* total vaginal length.

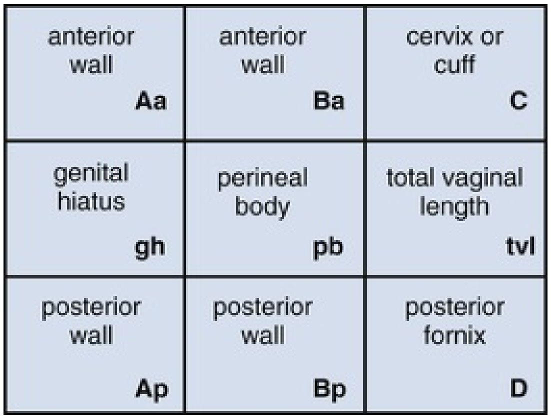
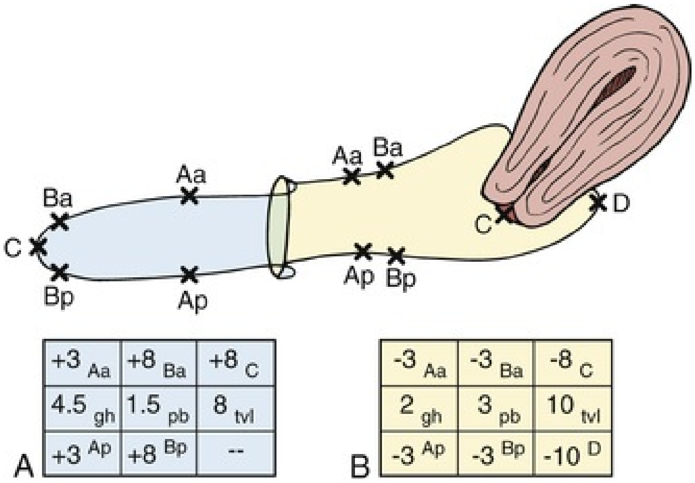
The 9-point scoring system is placed on a three-by-three grid (Fig. 115.5; Bump et al., 1996). Once the measurements are taken, patients are assigned to the corresponding stage. Stages are assigned according to the most severe portion of the prolapse on maximal strain. **Stage 0** is the absence of prolapse (points Aa, Ba, Ap, Bp are −3, and point C and D are between −tvl and −[tvl −2]cm). **Stage 1** prolapse is when the most distal portion of the prolapse is more than 1 cm above the level of the hymen. In **stage 2**, the most distal portion of the prolapse is situated between 1 cm above the hymen and 1 cm below the hymen (between −1 and +1). In **stage 3**, the most distal portion of the prolapse is more than 1 cm beyond the hymen but everted at least 2 cm less than the total vaginal length (tvl−2), and not all the vagina has prolapsed (> +1 but < +[tvl−2]cm). **Stage 4** is the complete eversion or eversion at least within 2 cm of the total vaginal length (≥ +[tvl −2]cm). Fig. 115.6 demonstrates POPQ measurements in a woman with normal anatomy and a woman with stage 4 post-hysterectomy vaginal vault prolapse. A simplified POPQ can be used, which is based on the POPQ with similar ordinal staging, but only four points are measured instead of nine. It is performed in the dorsal lithotomy position with the patient performing Valsalva. The only points measured are the Ba, Bp, C, and D (in non-hysterectomized patients) (Haylen et al., 2016).



anterior wall **Aa**	anterior wall **Ba**	cervix or cuff **C**
genital hiatus **gh**	perineal body **pb**	total vaginal length **tvl**
posterior wall **Ap**	posterior wall **Bp**	posterior fornix **D**

FIG. 115.5 The 9-point Pelvic Organ Prolapse Quantification scoring system placed on a 3 × 3 grid. *gh,* Genital hiatus; *pb,* perineal body; *tvl,* total vaginal length.



A

+3 Aa	+8 Ba	+8 C
4.5 gh	1.5 pb	8 tvl
+3 Ap	+8 Bp	--

B

-3 Aa	-3 Ba	-8 C
2 gh	3 pb	10 tvl
-3 Ap	-3 Bp	-10 D

FIG. 115.6 (A) Pelvic Organ Prolapse Quantification (POPQ) description of patient with total vault eversion posthysterectomy. (B) Woman with no prolapse (normal POPQ measurements). *gh,* Genital hiatus; *pb,* perineal body; *tvl,* total vaginal length.

A comprehensive history and physical examination with POPQ system are usually sufficient to properly assess the degree of prolapse. Most patients require little additional testing to specifically evaluate the prolapse. Radiology studies to establish the extent or to characterize a patient's prolapse are generally unnecessary. Pelvic ultrasound can be useful to identify pelvic organ abnormalities and identify possible mesh in the pelvis in patients with prior surgeries for prolapse or incontinence. The use of ultrasound to evaluate anatomic defect in POP is considered investigational by most (Barry and Dietz, 2005). For women with incomplete bowel emptying, significant defecatory dysfunction or when physical examination and prolapse severity does not correlate with symptoms, defecography, sometimes combined with dynamic magnetic resonance imaging (MRI) can be used (Rao, 2010). The resting and straining MRI can be particularly helpful in identifying the presence of enterocele (Fig. 115.7A and B). However, the benefit of routine use of MRI to describe the location of pelvic-support defects before attempting surgical repair has yet to be demonstrated to be necessary, cost effective, or result in superior outcomes and therefore still should be used at the discretion of the treating physician. **For the majority of patients, a careful POPQ physical examination and, if necessary, reassessment at the time of surgery remain the cornerstones of POP assessment.**

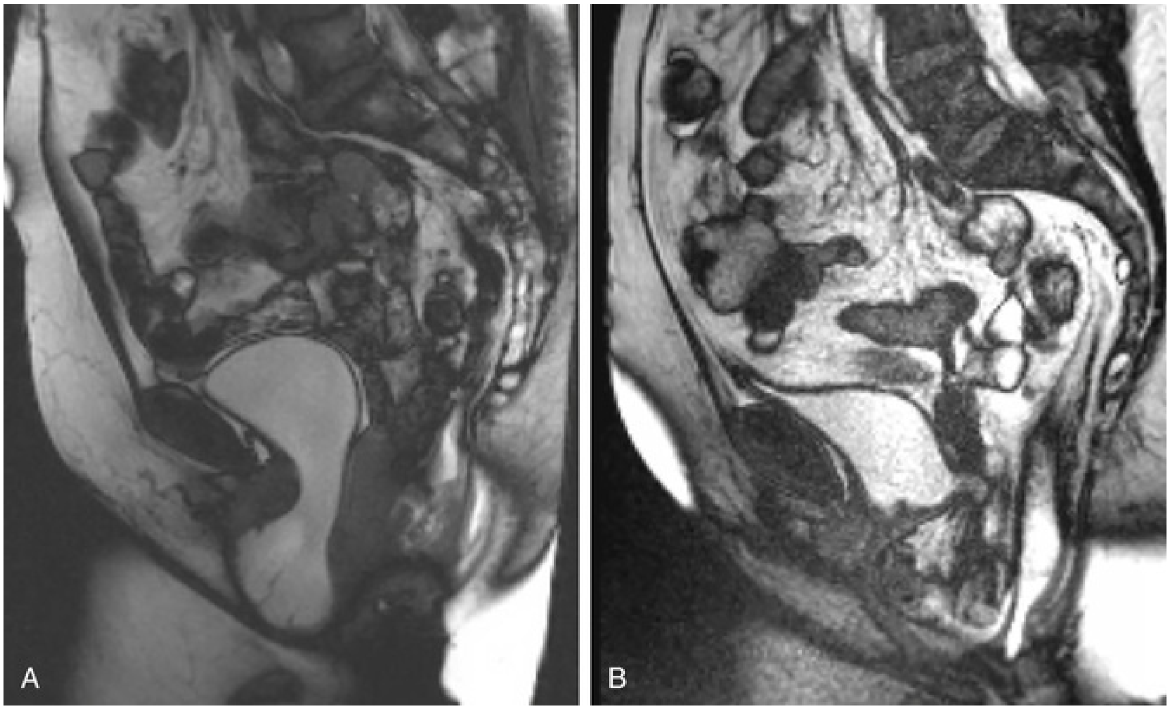


FIG. 115.7 (A) Magnetic resonance imaging (MRI) defecography of female with severe cystocele and uterine descent. (B) MRI defecography of female with defecatory dysfunction and severe enterocele.

Key Points: Definition and Classification of Pelvic Organ Prolapse

- POP should be described using anterior vaginal wall, uterine, apical, or posterior vaginal wall prolapse. Terms such as “cystocele, rectocele, enterocele, and urethrovesical junction prolapse” should be avoided.
- The POPQ system should be used to record the stage or prolapse.
- A careful POPQ physical examination remains the cornerstones of POP assessment for the majority of patients.

Epidemiology of Pelvic Organ Prolapse

Prevalence and incidence of POP+ are difficult to estimate because epidemiologic studies or the incidence and prevalence of this disorder are rare (Hunskaar et al., 2005). The prevalence of POP also varies depending on the definition used. This lack of a good definition stems in part from a poor understanding of what represents normal versus abnormal pelvic organ support in women. It is difficult to identify POP based on symptoms alone because symptoms experienced by patients with POP do not necessarily correlate with the location and the severity of the prolapse (Ellerkmann et al., 2001). Furthermore, prolapse often does not become symptomatic until it reaches the hymenal ring. Loss of vaginal or uterine support in women visit can be seen in up to 43% to 90% of patients (Durnea et al., 2014; Samuelsson et al., 1999; Swift et al., 2005). It is now clear that stage 1 prolapse of the anterior and posterior vaginal wall are so common that they are likely to be part of the normal spectrum. In a multicenter observational study of 1004 patients seeking routine gynecologic care, only 24% of patients had no prolapse. The prevalence of stage 1, 2, and 3 prolapse was 38%, 35%, and 2%, respectively (Swift et al., 2005). Thus some loss of uterovaginal support is present in the majority of adult women. Prolapse symptoms are typically not present until the prolapse reaches the hymen (Dietz and Mann, 2014; Swift et al., 2005). **Therefore asymptomatic stages 1 to 2 POP are considered normal in adult women and rarely require treatment.** Similarly, in the Women's Health Initiative, which measured prolapse in postmenopausal women with physical examination, the overall presence of any degree of prolapse was 41% for women with a uterus and 38% of women post-hysterectomy (Hendrix et al., 2002). Anterior vaginal wall prolapse was the most common single site of prolapse, seen in 34%. Posterior compartment prolapse was present in 19% of women and uterine prolapse in 14%. **Prolapse occurs most frequently in the anterior compartment, followed by the posterior compartment, and least commonly in the apex.** However, it is possible that apical prolapse has been underdiagnosed or underreported. It has become clear that apical prolapse is almost always present when there is significant anterior and posterior vaginal wall prolapse (Elliott et al., 2013; Rooney et al., 2006). This is particularly true for anterior vaginal wall prolapse. In a retrospective study, Elliott et al. confirmed that clinically significant apical vaginal prolapse incased significantly with increased anterior vaginal wall prolapse. Significant apical prolapse (C of −3 or greater) was reported in 42%, 85%, and 100% of patient with stage 2, 3, and 4 anterior vaginal wall prolapse respectively. **Surgeons planning cystocele repair should have a high degree of suspicion for vaginal apical prolapse and should consider concomitant vault suspension repair.**

The prevalence of prolapse based on sensation of a vaginal bulge, pressure, or protrusion or visible bulge from the vagina has been reported to be between 3% and 12% (Nygaard et al., 2008; Rortveit et al., 2007; Slieker-ten Hove et al., 2009; Wu et al., 2014). However, questionnaire-based estimates likely under-report the true prevalence of POP compared with incidence based on physical examination. This can be due to the fact that women often feel ashamed of their prolapse and are uncomfortable speaking about it with anyone, including physicians (Dunivan et al., 2014a). Furthermore, the degree of bother varies significantly among women. Whereas some women will be greatly symptomatic with a stage 2 prolapse, others will have no symptoms whatsoever. Some evidence suggests that symptoms severity and distress can vary according to the ethnic background. Dunivan et al. (2014b) reported that among women with stage 2 prolapse, Hispanic and Native American women experienced a higher degree of bother compared with non-Hispanic white women. However, the level of bother was not different between ethnic groups for prolapse stage 3 or greater.

A few studies have reported the natural history of POP. In a subgroup analysis of women enrolled in the Women's Health Initiative Estrogen Plus Progestin Trial and followed for 2 to 8 years, Handa et al. (2004) found that the annual incidences based on physical examination of new cystoceles, rectocele, and uterine prolapse were 9.3, 5.7, and 1.5 cases per 100 women-years. Their data also suggested that spontaneous regression was common, especially for grade 1 prolapse. In a group of symptomatic women who declined intervention and elected for observation, minimal change in prolapse staging was found during the observation period. After a median follow-up of 16 months (6–91), only 19% of patients demonstrated progression, 78% demonstrated no change, and 3% demonstrated regression (Gilchrist et al., 2013). **Generally, the natural history of pelvic organ prolapse is one of very slow progression, if at all, over time, even among symptomatic patients with advanced prolapse.**

Risk Factors for Pelvic Organ Prolapse

Many risk factors for pelvic organ prolapse have been suggested, and it seems most plausible that the cause is multifactorial. Vaginal childbirth, advancing age, and obesity are the most well-established risk factors for POP. Vaginal childbirth is the factor the most frequently associated with prolapse. The Oxford Family Planning Study was a prospective cohort study of more than 17,000 women. In this study, parity had the strongest association with the development of POP, with an adjusted relative risk of 8.4 for a woman who had delivered two children and 10.85 for someone who had delivered four or more children (95% confidence interval [CI] 4.65 to 33.81) (Mant et al., 1997). The Women's Health Initiative also demonstrated a strong association between parity and POP. A single childbirth was associated with raised odds of uterine prolapse (odds ratio [OR] 2.13; 95% CI 1.67–2.72), cystocele (OR 2.22; 95% CI 1.84–2.68), and rectocele (OR 1.91; 95% CI 1.67–2.19). Every additional delivery up to five births increases the risk of prolapse by 10% to 20% (Hendrix et al., 2002). In a case control study, women who had a vaginal delivery had an odds ratio of 2.9 of undergoing surgery for POP (95% CI 0.9–10.0), and women who had forceps delivery had an odds ratio of 5.4, suggesting certain aspects of vaginal delivery may affect the development of POP (Moalli et al., 2003). Another factor associated with the need of prolapse surgery in that study was age younger than 25 years at the time of first delivery. Interestingly, infant birth weight of greater than 4000 g was not associated with the need for prolapse surgery in this study. Substantial associations between delivery mode and symptoms and signs of prolapse were also demonstrated in a retrospective observational study by Trutnovsky et al. (2016). Nulliparous women showed the lowest prevalence of prolapse, followed by women who exclusively delivered by cesarean sections. The highest prevalence of prolapse was found in patients who delivered at least once by forceps and normal vaginal delivery. Compared with women who had delivered by cesarean sections only, the adjusted odds ratios for reporting symptoms of prolapse were 2.4 (95% CI 1.30–4.59) and 3.2 (95% CI 1.65–6.12) in the normal vaginal delivery with or without vacuum extraction and forceps groups, respectively.

Cesarean section seems to be protective against prolapse, but the degree to which cesarean delivery prevents the development of POP is unclear. In a cross-sectional study by Lukacz et al. (2006), there was no significant difference in the prevalence of prolapse between the cesarean delivery and nulliparous groups. In addition, there was an increased prevalence of prolapse in the labored cesarean group compared with unlabored cesarean group, which was similar to the rate of prolapse in the vaginal delivery group. This indicates that cesarean delivery after labor may not eliminate the risk of future symptomatic POP. Lukacz et al. calculated that the proportion of prolapse that could be prevented with a policy of routine elective cesarean section was 46% in this population.

The incidence and the prevalence of POP increase with advancing age (Hunskaar et al., 2005). In a cross-sectional study of 1004 US women aged between 18 and 83 years who saw their doctors for a yearly examination, the relative prevalence of prolapse rose by about 40% with every decade of life (Swift et al., 2005). In the Women's Health Initiative, women between the ages of 60 and 69 and 70 and 79 had a higher risk of prolapse than women aged between 50 and 59 years old (Hendrix et al., 2002). The risk of requiring surgery for POP and urinary incontinence also increase with age, peaking in the seventh decade (Olsen et al., 1997).

Obesity also has a role in the development of pelvic organ prolapse. In the same study by Hendrix et al., being overweight was associated with a significant increase in the occurrence of uterine prolapse by 31%, rectocele by 38%, and cystocele by 39%. Obesity was also associated with a significantly increased risk of uterine, posterior, and anterior prolapse 40%, 75%, and 57% increase, respectively. Waist circumference of at least 88 cm was similarly associated with an increased risk of rectocele and cystocele. Similar findings were also demonstrated by Swift et al., who noted that patients with a BMI between 25 and 30 kg/m^2 and more than 30 kg/m^2 had increased odds of developing POP (OR 2.51, 95% CI 1.18–5.35) and 2.56 (OR 2.56, 95% CI 1.23–5.35), respectively (Swift et al., 2005).

Hysterectomy is associated with an increased risk of developing POP. Interestingly, when the indication for hysterectomy is prolapse, a higher risk of subsequent POP surgery has been noted (Lykke et al., 2015). In the Oxford Family Planning Study (Mant et al., 1997), the cumulative risk of surgery for prolapse in women who had undergone a hysterectomy was 29 per 1000 women-years versus 16 per 1000 women-years for the entire cohort. The cumulative risk rose from 1% at 3 years after a hysterectomy to 5% 15 years after hysterectomy. The risk of prolapse was the highest, 5.5 times higher, for patient who had undergone previous hysterectomy for prolapse compared to other reasons. Hysterectomy performed for POP is a strong predictor of the need for repeat pelvic floor surgery, although this in part may be a result of failure to perform concomitant vaginal vault suspension at the time of hysterectomy.

Some evidence suggests that **race** plays a role in POP. Black women have the lowest prevalence of POP, and Hispanic women have the highest prevalence after controlling for possible confounding factors. Based on physical examination, Hendrix et al. (2002) found that Hispanic and Asian women had increased risks of developing cystocele (Hispanic, OR 1.20, 95% CI 1.05–1.36; Asian, OR 2.18, 95% CI 1.8–2.64) compared with white individuals. African-American women had a lower risk (OR 0.65, 95% CI 0.59–0.73). Based on symptoms, Rortveit et al. (2007) found ORs of 0.4 (95% CI 0.2–0.8) for African-American and 1.3 (95% CI 0.8–2.2) for Hispanic women, with white women as the reference group.

Other factors have also been studied in relation to POP risk. An association between **maximum birth weight** and the development of POP has also been found, although not consistently (Moalli et al., 2003; Samuelsson et al., 1999). **Menopause** has been cited often as a risk factor for prolapse. However, studies investigating the relationship between hormonal status and prolapse have failed to consistently find an association between estrogen status and POP (Mant et al., 1997; Nygaard et al., 2004). Some evidence suggests that **heritable or genetic factors** can play a part in the development of POP. One study reported a higher risk of prolapse in women with a mother or a sister of reporting prolapse (Chiaffarino et al., 1999). Others have shown a fivefold increased risk of prolapse among siblings of women with severe prolapse compared with the general population (Jack et al., 2006). **Chronic constipation** has been also associated with pelvic organ prolapse. In a population-based study by Rortveit et al. (2007), chronic constipation was found to be a factor independently and significantly associated with symptomatic prolapse, with a 2.5-fold increase risk. Other factors have been linked inconsistently with prolapse, such as smoking, heavy lifting, intense physical activity, and chronic pulmonary disease (Vergeldt et al., 2015).

Key Points: Epidemiology of Pelvic Organ Prolapse

- The prevalence of symptomatic prolapse ranges from 3% to 12%, although asymptomatic prolapse is present in the majority of adult women.
- Anterior compartment prolapse is the most frequent location of prolapse.
- The incidence and prevalence of POP increase with age, as do rates of surgery for POP.
- Parity is associated with an increased risk for POP later in life. The risk of

POP increases with every additional vaginal childbirth. Forceps delivery increases further the risk of developing POP.

- Elective cesarean section or unlabored cesarean section seems to be protective against prolapse.
- Obesity is a major risk factor for the development of POP.
- Hysterectomy, especially when performed for prolapse, increases the risk for POP and is a strong predictor of secondary pelvic floor surgery.
- POP is more common in Caucasian and Hispanic women when compared with African-American women.
- Other factors associated with the development of POP include maximum birth weight, menopause, genetic factors, and chronic constipation.

Relationship Between Urinary Incontinence and Pelvic Organ Prolapse

Etiologic risk factors for UUI and SUI overlap with the risk factors for POP. In fact, more than 40% to 55% of women with SUI will have a significant anterior vaginal prolapse, and almost 20% of patients with OAB symptoms will have an anterior vaginal wall prolapse (Cardozo and Stanton, 1980; Norton et al., 2014).

Community and hospital-based studies noted that the prevalence of OAB symptoms was higher in patients with prolapse than without prolapse (de Boer et al., 2010). However, no relationship was found between the compartment or the stage of the prolapse and the presence of OAB symptoms. Improvement in OAB symptoms can be expected after prolapse surgery. In fact, up to 69% of women experience an improvement in their OAB symptoms after prolapse surgery (de Boer et al., 2010). In fact, Fletcher et al. (2010) found that anterior compartment repair resulted in a reduction of frequency (by 33%), UUI (49%), and difficulty voiding (74%) at a median of 21 months’ follow-up. However, the results of the various studies that tried to identify predictors for the resolution of OAB symptoms after prolapse surgery were inconclusive (de Boer et al., 2011). **It is still impossible to reliably predict the presence or persistence of OAB symptoms after prolapse surgery.** The pathophysiology of OAB in women with pelvic organ prolapse is still unclear. BOO is likely the most important mechanism by which prolapse induces OAB symptoms. Chronic stretching of the bladder wall is likely also to occur with vaginal prolapse, which could be a factor in the development of detrusor overactivity. One theory suggests that a severe cystocele can put traction of the urethra, which opens the bladder neck. This may allow urine to enter the urethra and causes detrusor overactivity (Jung et al., 1999).

More than half of women with SUI will also have POP. In the Trial of Mid Urethral Slings (TOMUS), a multicenter National Institute of Diabetes and Digestive and Kidney Diseases (NIDDK)-sponsored study assessing the efficacy and safety of two types of mid-urethral sling for the treatment of stress urinary incontinence, stage 2 POP was present in 49% of patients and stage 3 prolapse was present in 6% of patients at baseline. Even though the majority of patients with stage 3 prolapse were symptomatic (78%), only 25% of patients with stage 2 prolapse reported symptoms (Norton et al., 2014). Of the asymptomatic women with stage 2 prolapse, 15% underwent a concomitant prolapse repair at the time of the sling surgery. **Failure to recognize POP at the time of UI treatment may greatly increase the need for subsequent surgery for POP** (Anger et al., 2007). Data from a 5% national random sample of 1999 to 2001 Medicare claims for patients undergoing UI surgery showed that urologists performed concomitant prolapse repairs at the time of sling in 29.1% of cases, whereas gynecologists performed prolapse repairs in 55.7% ($P < 0.0001$). In the 12 months after sling surgery, patients who underwent surgery by a urologist were more likely to undergo a repeat surgery for prolapse (26.0% vs. 12.2%, $P < 0.0001$). These findings emphasize the importance of identifying and managing symptomatic prolapse when evaluating patients with UI.

In addition, previously continent women can also develop de novo SUI after POP surgery. Up to a quarter of patients with advanced prolapse may have such **"occult" stress urinary incontinence** (Brubaker et al., 2006). Cystocele can create a kink at the level of the urethra, causing urethral obstruction. Treating the prolapse may resolve the obstruction, which can then lead to the "unmasking" of SUI. It is also not uncommon to notice an improvement of stress incontinence symptoms as the prolapse stage progresses in severity. Urodynamic study performed with prolapse reduction can help to identify occult stress incontinence and help guide treatment planning. Visco et al. (2008) selected a subgroup of patients from the Colpopexy and Urinary Reduction Efforts (CARE) trial and assessed stress-continent patients with stages 2 to 4 prolapse who underwent urodynamic study with prolapse reduction to estimate if urodynamic study with prolapse reduction can predict postoperative stress incontinence. Overall, of those found to have stress incontinence during prolapse reduction during urodynamics, 58% of patients who did not undergo a concomitant Burch colposuspension at the time of sacrocolpopexy developed postoperative stress incontinence, compared with 38% of those in whom a colposuspension was performed ($P = 0.04$). Preoperative SUI during urodynamic study with prolapse reduction is associated with a higher risk of postoperative stress incontinence after prolapse repair. Similar findings were also revealed in the Outcomes Following Vaginal Prolapse Repair and Midurethral Sling (OPUS) trial (Wei et al., 2012). This trial randomized women without symptoms of SUI to receive a concomitant mid-urethral sling (vs. sham) at the time of vaginal prolapse surgery. At 1 year after surgery, incontinence was present in 27.3% of women in the sling group compared with 43% in the sham group ($P = 0.002$). The number needed to treat with a sling to prevent one case of urinary incontinence at 12 months after prolapse surgery was 6.3. However, complications were increased among those who underwent a sling, including bladder perforation in 6.7% (vs. 0), UTI (31.0% vs. 18.3%), major bleeding complications (3.1% vs. 0), and incomplete bladder emptying 6 weeks after surgery (3.7% vs. 0, $P \leq .05$ for all comparisons). **These studies emphasize the relationship between anterior vaginal prolapse and SUI. Prophylactic sling placement at the time of POP surgery for women who do not report SUI reduces the risk of de novo stress incontinence after surgery but increases the likelihood of adverse events. Counseling of women who are planning to undergo prolapse surgery should include benefits and potential additional risks associated with prophylactic sling placement.**

Key Points: Conditions Associated With Pelvic Organ Prolapse

- More than 40% of women with SUI and 20% of women with OAB symptoms will have an anterior vaginal wall prolapse.
- Occult SUI is stress incontinence only observed after the reduction of coexistent prolapse. Failure to address occult SUI at the time of surgery for POP may lead to more severely symptomatic SUI postoperatively.

Consequences of Urinary Incontinence and Prolapse

Societal Costs of Urinary Incontinence

The costs of diagnosing and treating UI are significant, as are personal hygiene-related costs. Estimates of cost are difficult to make because they include many variables not easily quantified in health care cost analyses, including many out-of-pocket expenses that place the financial burden squarely on individuals rather than on government or third-party payers. Therefore, in addition to the costs of diagnostic studies, office visits, medications, surgeries, and other interventions, and treatment of related UTIs or care for skin breakdown, one must take into account personal expenses related to absorbent products, increased laundering related to leakage, missed work, and other personal costs. **A review of the financial burden associated with the management of female SUI alone reported annual costs in excess of $12 billion in the United States, with more than 70% considered out-of-pocket expenses** (Chong et al., 2011). A report from the Urinary Incontinence Treatment Network noted that women with severe incontinence had $900 of out-of-pocket expenses annually for incontinence routine care, and a mean reduction of $625 was noted after surgical intervention (Subak et al., 2006, 2014). **With regard to OAB, if one uses a prevalence estimate of 42 million Americans affected, a societal cost of $25 billion annually has been estimated** based on outpatient visits, medical treatments, work time lost, and other related expenses (Onukwugha et al., 2009).

Social Impact of Urinary Incontinence

Nearly every aspect of a patient's life is affected by UI (Coyne et al., 2012). Relationships are affected, and sexual activity may be curtailed by the threat of UI. Adults of all ages and their partners are affected by the impact of UI on sexual activity, and surgery to improve incontinence has a positive effect on sexual function (Brubaker et al., 2009; Mengerink et al., 2016; Nilsson et al., 2009). Patients often avoid travel, restrict what they eat and drink (and inappropriately dehydrate themselves), alter what they wear (wearing dark clothing to guard against obviating leakage), and avoid contact with strangers.

They may have decreased work productivity because they need to urinate often (or desire to urinate to try to avoid leakage episodes). Because sleep disturbances are more common in some forms of UI, daytime alertness and productivity may be affected as well.

UI appears to affect the QoL of patients at all ages. Young nulligravid women with incontinence report greatly diminished overall well-being compared with age-matched women without UI (O'Halloran et al., 2012). Elderly patients are affected as well, with the severity of UI rather than the type of UI primarily responsible for the impact on QoL (Aguilar-Navarro et al., 2012; Barentsen et al., 2012). **The impact of UI is seen in nearly all QoL domains, and the severity of impact may be greater than that seen with other common conditions associated with aging, including arthritis and diabetes** (Hawkins et al., 2011). As for the most bothersome LUTS, a population-based study of more than 3700 men and women confirmed that urgency and urgency incontinence are the most troublesome overall (Agarwal et al., 2014).

Key Points: Consequences of Urinary Incontinence

- Societal costs of UI are difficult to estimate, but at least tens of billions of dollars are spent on UI. Costs include incontinence/hygiene products, medical and surgical treatments, office visits, decreased work productivity, and others.
- Interpersonal relationships are affected by UI. Sexual activity may be curtailed because of concerns regarding incontinence.
- Almost all QoL domains are affected by UI. Travel, leisure, and recreational activities are often curtailed. Diet is often altered and fluids may be inappropriately restricted.
- Sleep disturbances are associated with certain types of UI.

Impact of Pelvic Organ Prolapse on Quality of Life

POP has a significant negative impact on QoL. Similar to UI, POP is often not discussed freely in public. Women may experience shame about the condition and are often uncomfortable discussing it, even with their own physician

(Dunivan et al., 2014a). Women seeking treatment for POP have decreased body image and overall QoL. Body image has been shown to be an important determinant of QoL in patients with prolapse (Jelovsek and Barber, 2006). Svihrova et al. (2014) evaluated the impact of pelvic organ prolapse on quality of life by estimating the disability-adjusted life-years (DALYs) lost as a result of symptomatic prolapse. It was estimated that prolapse caused the loss of 14.5 DALYs per woman in middle-aged women because of disability. Surgical intervention has been proven to improve loss of QoL associated with POP (Doace et al., 2014).

POP also negatively affects sexual function. It has been estimated that 38% of women with prolapse avoid intercourse as a result of their condition (Barber et al., 2002). Women with both POP and UI are more likely to report decreased libido, decreased sexual excitement, and difficulty achieving orgasm during intercourse when compared with women with UI alone (Özel et al., 2005).

Financial Impact of Pelvic Organ Prolapse

Olsen et al. (1997) reported an 11% lifetime risk of undergoing a single operation for POP and UI in American women. It was also found that reoperation for recurrent prolapse and incontinence was common (29%). Smith et al. (2010) reported a 19% lifetime risk of undergoing prolapse surgery in Western Australia. POP is the most common indication for hysterectomy among women over the age of 54 in the United States (Wilcox et al., 1994). In 1997 the direct costs of POP surgery were $1.012 billion, including $494 million (49%) for vaginal hysterectomy, $279 million (28%) for cystocele and rectocele repair, and $135 million (13%) for abdominal hysterectomy (Subak et al., 2001). Urinary incontinence procedures were performed in 21% of prolapse operations, accounting for $218 million. Given the aging of the population, POP will represent an even greater public health burden in the next few years, given that aging women appear to be the fastest-growing population (He et al., 2005). It has been estimated that the number of American women with at least one pelvic floor disorder will also increase from 28.1 million in 2010 to 43.8 million in 2050, and the number of women with POP will increase by 46% (Wu et al., 2009). Using the 2007 Nationwide Inpatient Sample and the 2006 National Survey of Ambulatory Surgery, Wu et al. (2011) calculated the rates for inpatient and outpatient SUI and POP surgery from 2010 through 2050. They estimated that the number of patients who will have surgery for prolapse will increase

48%, from 166,000 in 2010 to 245,970 in 2050. These data suggest that surgeons will be faced with a much higher demand for prolapse and incontinence procedures over the upcoming several decades.

Physiology of Urinary Continence

Overview of Normal Continence Mechanisms

Urinary continence is maintained via an interplay of complex neural, structural, and ultrastructural mechanisms involving the lower urinary tract and surrounding structures. Failure of any one of these contributing factors can lead to UI. Diseases and their treatments, as well as aging, may affect more than one of these mechanisms, leading to UI. For example, diabetes, particularly when poorly controlled, can lead to UI initially mitigated, in part, by hyperglycemic polyuria. Later, with microvascular changes and resultant oxidative stress, direct neurogenic and myogenic changes occur, which may result in UUI and SUI.

Neural Control of the Lower Urinary Tract

Bladder storage at its very essence is a neurologically mediated event. **Parasympathetic transmission (via the pelvic nerve) is suppressed and sympathetic transmission (via the hypogastric nerve) is active, and both are imperative to the creation of a low-pressure reservoir that is maintained during the entirety of the filling phase.** Spinal reflex mechanisms allow afferent signaling from the bladder (via A delta myelinated nerves) to promote sympathetic-mediated closure of the bladder neck, a closure mechanism that is decidedly stronger in men than in women. The pontine micturition center in the brainstem integrates afferent input and ultimately is responsible for parasympathetic-mediated bladder contraction (Drake et al., 2010). However, before a coordinated contraction, tonic inhibition of coordinated parasympathetic activity by suprapontine centers prevents bladder contraction. In addition, ongoing pudendal nerve activation (via Onuf nucleus in the sacral cord) of the external sphincter mechanism results in the continuous resistance required to maintain continence during bladder filling.

Bladder: an Organ Capable of Significant Expansion at Low Pressures

The position of the bladder also provides a unique ability to allow for

significant expansion while placing the vulnerable sphincteric unit in a more protected environment where external forces are less likely potentially to influence the ability of the outlet to maintain continence (particularly in men). The dome of the bladder can expand well into the peritoneal cavity with relatively no extravesical force opposing this expansion. In contrast, the bladder base and neck sit in a stable retropubic location. In men, this position is fixed and immobile, and unless neurologic/traumatic/operative events occur, only a direct impact on the sphincteric unit will result in leakage. In women, in whom pelvic floor laxity can affect bladder neck position and function, incontinence may result, at least in part, from changes in the position of the bladder outlet.

The structure of the bladder wall and characteristics of smooth muscle cells allow for passive filling without increases in pressure that would create undue forces on the bladder outlet. **Relatively poor coupling between detrusor smooth muscle cells appears to contribute to the ability of the bladder to avoid the propagation of unplanned spontaneous smooth muscle contractions into a coordinated bladder contraction during filling.** Although individual smooth muscle cells may be triggered to contract by stretching during bladder fill, in most situations a sustained bladder contraction requires coordinated parasympathetic stimulation. The multiple-layered mucosal lining of the bladder further enhances the ability of the bladder to store urine, as the urothelial cell layers ("umbrella cells") can flatten considerably with filling. Further, **the extracellular matrix composition of the bladder wall, and in particular the type of collagen (type I favored in normally compliant bladders), as well as the collagen-to-elastin ratio, are critical to the maintenance of a low-pressure state in the bladder during normal filling, with elastin in particular contributing to compliance** (Lemack et al., 1999).

Key Points: Factors Contributing to Low-Pressure Reservoir During Bladder Filling

- **Neural:** Parasympathetic suppression, sympathetic activation promotes detrusor relaxation.
- **Anatomic (gross):** Intraperitoneal position of bladder dome permits unimpeded expansion.
- **Anatomic (micro):**

- Multilayered mucosal layer of bladder promotes expansion with filling, collapse with emptying.
- Poor coupling between detrusor smooth muscle cells dissipates aberrant contractions.
- Extracellular matrix composition promotes minimal change in bladder pressure by enhancing bladder elasticity. Collagen type I is major collagen subtype. Elastin content is critical in maintenance of bladder compliance.

Bladder Outlet and Sphincteric Mechanisms

Maintenance of a low-pressure reservoir would be of no value in ensuring continence if not for the presence of sufficient outlet resistance (higher than storage pressures). **A competent bladder outlet results from specific urethral mucosa attributes, which are the so-called internal sphincter (intrinsic properties of the bladder neck/proximal urethra) and the distal (rhabdo) sphincter.** Urethral mucosal longitudinal folds allow for distensibility (for opening during voiding) and contribute to the creation of a mucosal “seal” that enhances urethral closure during bladder filling. The well-vascularized spongy submucosal layer contributes to the distensibility of the urethral lumen. In addition, there are important structural and functional differences characterizing the sphincteric units in men and women that help to explain further how incontinence can be maintained in each of the sexes.

Male Sphincteric Mechanisms

The internal sphincter is a contributory continence mechanism extending from the bladder neck to the distal verumontanum. In the absence of disease, injury, or prior surgery, urine does not descend beyond the bladder neck to the level of the external sphincter. Dryness created by the forces at the bladder neck is, in part, a result of α-adrenergic activation of smooth muscle at the bladder neck and within the prostatic urethra. This smooth muscle extends distally and then toward the rhabdosphincter, where the greatest intraurethral forces are generated (Koraitim, 2008). **Sympathetic activation of α receptors in this zone, when combined with β-adrenergic–stimulated relaxation of the bladder body, promotes dryness**. Other aspects of the internal sphincter continence unit include the prostate, which further enhances outlet resistance. Because of these factors, loss of external sphincter function, such as with traumatic pelvic injury, may not result in incontinence in men with an intact bladder neck. This is in contradistinction to the bladder neck in women, which is relatively weak, making women more vulnerable to incontinence with any deficiency of external sphincter function. An artist's rendering of the male sphincteric unit, with accompanying histologic dissections in shown in Fig. 115.8 (Schwalenberg et al., 2010).

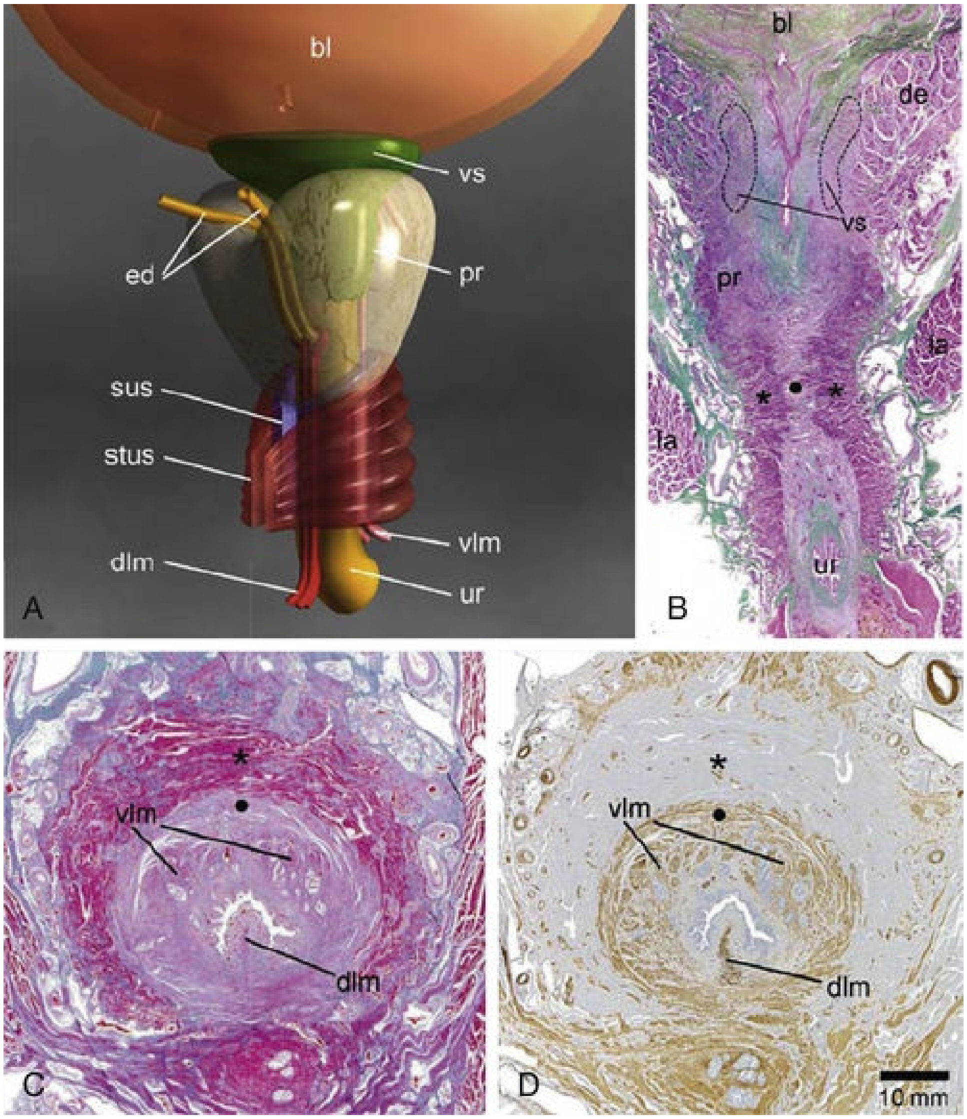

FIG. 115.8 Male urethral sphincter complex artist rendering (A) with accompanying histologic sections (B–D). Bladder *(bl),* bladder neck/internal sphincter *(vs),* ejaculatory ducts *(ed),* prostate *(pr),* rhabdosphincter *(stus),* smooth muscle component of urethral sphincter *(sus),* urethra *(ur),* ventral (inner) longitudinal muscle of urethra *(vlm),* and dorsal (inner) longitudinal muscle of urethra *(dlm)* shown. *Circle* and *asterisk* represent internal smooth muscle and external striated muscle components of the external

urethral sphincter complex, respectively.

The external sphincter is composed largely of skeletal muscle and, as such, has the ability to create intense compressive forces. Indeed, pressures at the rhabdosphincter are in excess of 40 cm H_2O continuously during bladder filling, and these pressures can rise considerably further with voluntary contraction. Pudendal nerve injury or denervation can result in the loss of external sphincter strength and subsequent UI (Gill et al., 2013; Sajadi et al., 2012). The strength of the external sphincter is highlighted in the presence of the failure of and/or the injury to the bladder neck (i.e., during TURP), in which case the presence of an intact rhabdosphincter nearly always results in the maintenance of continence. **The rhabdosphincter is a concentric muscle composed largely of type I (slow-twitch) skeletal muscle**, although smooth muscle fibers are noted to intermingle with the more prominent skeletal muscle bundles. **The presence of slow-twitch fibers is what is largely responsible for the tonic ability of the sphincter to maintain urethral closure essentially in a continuous fashion during bladder filling**. Fast-twitch fibers found in the surrounding levator musculature contribute then to the ability transiently to enhance voluntary closure during times of increased stress on the sphincteric unit. Further anatomic support of the rhabdosphincter is derived from the pubourethral ligaments, which anchor the sphincteric unit solidly in an anterior position. Ventral support of the sphincter comes from the condensation of musculofascial elements that ultimately fuse at the perineal body. This unique arrangement of the male sphincteric unit stabilizes and protects the sphincter from the impact of external forces.

Key Points: Continence Mechanisms of the Bladder Outlet and Urethra in Men

- Internal sphincter:
  - α-Adrenergic activation of bladder neck and prostatic smooth muscle
  - Prostatic restrictive forces on urethra
- External sphincter:
  - Rhabdosphincter (largely slow-twitch type I skeletal muscle) provides tonic compression.
  - Levator muscular elements (fast-twitch) assist during times of increased

stress on external sphincter.
- Anterior fixation by pubourethral ligaments
- Posterior support of musculofascial plate fusing at the perineal body

Female Sphincteric Mechanisms

Unlike the powerful continence zone created at the level of the bladder neck in men, continence in women is largely a result of forces created along the proximal urethra and/or mid-urethra, in addition to somewhat less forceful distal urethral muscular contributions. **Indeed it is fairly common for the bladder neck to be incompetent in women, although continence remains intact** (Chapple et al., 1989; Versi et al., 1990). As in men, longitudinal smooth muscle courses toward the external sphincter, although **the bulk of the muscle responsible for sphincteric control in women is circular striated muscle located in the proximal urethra and/or mid-urethra. Muscular forces (primarily striated muscle) create a nearly complete circumferential compression of the mid-urethra** (DeLancey, 1988) **under the influence of tonic pudendal simulation.** Experimental studies in rats have demonstrated transverse and longitudinal orientation of striated muscle inserting directly into the connective tissue of the urethral wall (Mondet et al., 2003) (indicating circular and longitudinal muscle orientation). Pudendal denervation and resultant sphincteric weakness, potentially occurring as a result of prolonged labor, is one mechanism by which incontinence may result from the effects of labor and delivery.

More distally, striated muscular fibers are not oriented circularly but are located ventrally. These muscular fibers contribute to the compressor urethra (which originates in the perineal membrane) and urethrovaginal sphincter (which originates in the vaginal wall). These further contribute to the sphincteric unit in women. Unlike the relative stability and immobility of the male external sphincter, the female sphincteric unit is most certainly vulnerable to common external forces.

A combination of attributes of the female urethra contribute to urinary continence. **Intrinsic properties of the urethral mucosa and urethral wall are an important part of maintaining continence in women. The spongy nature of estrogen-sensitive urethral submucosa enhances the apposition of urethral mucosa, which aids in the creation of an effective watertight seal.** In fact, it has been estimated that up to 30% of the forces responsible for continence are derived from this seal (Raz et al., 1972).

Surrounding musculofascial elements further support continence mechanisms in women. **A strong muscular backing (anterior vaginal wall) provides posterior support and additional compression of the mid-urethra.** Laxity in vaginal support can result in anterior vaginal prolapse and a shearing effect in the continence zone, particularly if anterior ligamentous support at the proximal urethra (pubourethral ligaments) is intact. **Indeed fixation of the urethra by ligamentous support (pubourethral ligaments) normally minimizes movement of the proximal urethra,** further contributing to continence by helping to prevent abdominal forces to be transmitted to the remainder of the urethra**. The urethropelvic ligaments further anchor the urethra to the tendineous arc bilaterally. It is the combined effect of these extraurethral forces, intrinsic urethral properties, and muscular elements that promotes continence, and loss of any one, or typically several, can result in UI in women.**

Key Points: Continence Mechanisms of the Outlet in Women

- **External sphincter mechanisms:**
    - Circular striated muscle of the external sphincter in the mid-urethra under pudendal innervation supplies the majority of active mid-urethral compression by the external sphincter.
    - More distally, longitudinal striated muscle arising from the vagina and perineal membrane contributes to sphincteric forces.
- **Urethral attributes:**
    - Mucosa of urethral wall tends to adhere to itself.
    - Spongy, vascular nature of urethral submucosal layer promotes apposition of the urethral wall.
- **Surrounding support structures:**
    - Anterior vaginal wall provides firm posterior support of the urethra allowing compression of the mid-urethra.
    - Fixation of the mid-urethra anteriorly by the pubourethral ligaments helps prevent transmission of intra-abdominal forces to the remainder of the urethra.
    - Further anchoring of the urethra anterolaterally to the arcus tendineus is

provided by the urethropelvic ligaments.

Pathophysiology of Urinary Incontinence: General Principles

Factors Affecting Bladder Storage

UI resulting from bladder dysfunction is induced by a variety of neurologic, iatrogenic, and common demographic risk factors. **Any neurologic process interrupting the normal suprapontine inhibition of the pontine micturition center may result in neurogenic detrusor overactivity (NDO) and cause UUI.** CVAs, multiple sclerosis, and Parkinson disease are among the more common neurologic processes that may result in UUI. DM, even early in diagnosis, has been associated with NDO and UUI. Obstruction resulting from anti-incontinence surgery in women can lead to de novo UUI secondary to induced detrusor overactivity (DO). In men, BOO induced by prostatic enlargement (or other obstructive process) can be associated with DO and resultant UUI.

Poor emptying from detrusor underactivity or detrusor areflexia (causing overflow incontinence) **can also cause UI**. This type of detrusor dysfunction is common with neurologic diseases affecting the lumbosacral cord or conus medullaris. Systemic diseases, which can result in peripheral neuropathies such as diabetes, tabes dorsalis, and alcoholism, can similarly cause overflow incontinence. Whereas early in the disease process DM can lead to UUI, later in the process sensation can be altered as can detrusor contractility, resulting in impaired bladder emptying, UTIs, and UI. Radical pelvic surgeries (i.e., radical hysterectomy, abdominoperineal resection) can also result in significant, sometime permanent, neurogenic detrusor dysfunction leading to urinary retention and overflow incontinence. Pelvic external beam radiation (commonly used in the treatment of prostate cancer and other pelvic malignancies) can alter bladder compliance, increase detrusor leak point pressure, and contribute to UI.

Factors Affecting Sphincteric Function

The most common causes of **intrinsic sphincteric deficiency (ISD)** are iatrogenic, although, less commonly, neurologic disease can directly affect sphincter function. Traumatic or vascular injury to the lumbosacral cord can impair sphincter function and can result in ISD (Gomelsky et al., 2003). Multiple systems atrophy typically results in loss of intrinsic sphincteric function in men and a high likelihood (≥20%) of UI after TURP in men who are considering this surgery. Other processes such as traumatic cervical or upper thoracic spinal cord injury can cause **detrusor sphincter dyssynergia,** creating impaired bladder emptying and UI, particularly when coupled with NDO. Medications used purposely to enhance voiding (alpha-blockers) can reduce outlet resistance sufficiently to cause leakage in vulnerable patients. Any medication with either α-antagonistic properties or skeletal muscle relaxant properties can also cause UI by inhibiting outlet resistance.

In women, urethral surgery or anti-incontinence surgery can lead to urethral scarring, periurethral fibrosis, and ISD. The likelihood of ISD appears to increase with an increased number of failed surgeries previously. Advanced prolapse surgery performed without concomitant treatment of the bladder outlet appears to result in an increased likelihood of postoperative UI. This appears to be true of abdominal sacrocolpopexy and vaginal surgery for significant anterior prolapse (Brubaker et al., 2008; Wei et al., 2012). Still, the risks of incontinence surgery, and the reality that some patients who never would have developed UI (and thus are overtreated) must be weighed against the risk of needing future surgery or the impairment of QoL associated with ongoing leakage.

Labor and delivery can also affect sphincter function in women. **Prolonged labor, third-degree lacerations, large birth weight, multiparity, and forceps deliveries are aspects of labor and delivery that have been associated with sphincteric dysfunction.** The mechanisms by which labor appears to result in UI include direct injury to ligamentous/fascial support, ischemic injury to the pelvic floor as a result of prolonged compression, pelvic or pudendal denervation induced by compression, and direct genitourinary injury. This finding is further corroborated by a study of women followed for decades after cesarean section compared with women who had a single vaginal delivery. Twenty years after delivery, women who underwent vaginal delivery are more likely to experience MUI, SUI, and UUI and are more likely to report severe forms of UI (Gyhagen et al., 2013a, b).

RP, the most common surgical cause of incontinence in men, generally causes leakage via a direct impairment of sphincter function. Among incontinent men studied urodynamically, ISD is the predominant finding in approximately 70%, whereas DO and altered compliance are less common causes, although they may contribute to the condition in more than 30% of cases (Dubbelman et al., 2012).

It is clear, however, that the finding of DO is common among men after RP (more than 50% of men 3 years after RP), regardless of the presence of UI (Song et al., 2010). After RP, decreases in functional urethral length (64%) and maximum urethral closure pressure (MUCP, 41%) have been noted. In this regard, higher baseline MUCP has been associated with earlier urinary control and lower likelihood of postprostatectomy incontinence (PPI) (Dubbelman et al., 2012). Although the approach of RP (open vs. robotic) does not appear to affect greatly the risk of ISD, preservation of the bladder neck and, in particular, nerve sparing for open and robotic approaches to RP seems to hasten the recovery of continence and to lower the overall likelihood of PPI (Campodonico and Manuputty, 2012; Srivastava et al., 2013).

Pathophysiology of Stress Urinary Incontinence in Women

Original theories explaining the pathophysiology of UI in women focused on the descent of the proximal urethra and bladder neck, and the implications of moving away from an intra-abdominal location with anterior pelvic prolapse. It was believed that as the urethra became hypermobile, intraperitoneal forces could no longer constrict the urethra and incontinence resulted (Enhorning, 1961). The pressure transmission theory was the basis of several effective operations (i.e., Marshall-Marchetti-Krantz and Burch colposuspension) designed to restore the urethra to its normal anatomic location.

Loss of Urethral Support

Gradually the understanding of the urethral support mechanisms and causative factors for SUI evolved. It became clear that urethral support emanated from the endopelvic fascia and was enhanced by anterior support (pubourethral ligament) and posterior support (vaginal wall), all of which normally prevent excessive urethral mobility. **Proponents of the current theory thought it best to explain incontinence resulting from urethral hypermobility as the "hammock hypothesis," based on the work of John DeLancey** (1994). **This theory suggests that posterior musculofascial fascial/ligamentous support of the urethra from the anterior vaginal wall and extending laterally from the vagina to the levator ani and arcus tendineus fascia pelvis contribute to the maintenance of continence seen at times of increases in intra-abdominal pressure** (Figs. 115.9 and 115.10). Compression of the urethra against this firm posterior backing (hammock) enables the urethra to prevent urinary loss with stress maneuvers. Loss of backing from this musculofascial support leads to incontinence because of an inability to compress the urethra, particularly if combined with intact anterior support (creating a shearing effect) and loss of compressive sphincteric forces (Mostwin et al., 1995). Therefore this theory suggests that repositioning the urethra, previously considered to be essential, is not necessarily essential to restoring continence in women who leak with SUI. The essential element to restoring continence, then, rests with restoring the layer of support to the posterior urethra and therefore allowing the urethra to be compressed adequately (DeLancey, 1997).

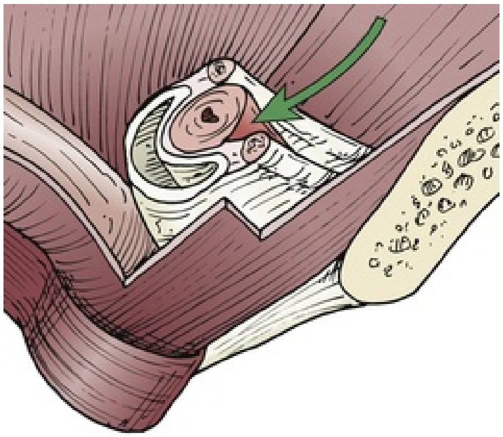

FIG. 115.10 Lateral view of the pelvic floor with urethra, vagina, and fascial tissues transected at the level of the vesical neck drawn from three-dimensional reconstruction, indicating compression of the urethra by downward force *(arrow)* against supportive tissues, indicating the influence of abdominal pressure on urethra.

Petros and Ulmsten (1990) proposed an additional explanation for SUI and UUI. **The "integral theory" pinpoints the site of the maximal continence zone in the mid-urethra at the pubourethral ligaments. During times of bladder storage, anterior forces from the pubococcygeus muscle pull the vagina up against the pubourethral ligament to close the urethra. In**

addition, backward forces stretch the vagina and bladder neck in a plane around the pubourethral ligament to allow proximal urethral closure (Petros and Skilling, 2001; Petros and Woodman, 2008). The authors contend that laxity of these forces secondary to connective tissue damage leads to the loss of urine with stress and, further, that muscular forces stretching the vaginal membrane against the ligaments activate stretch receptors, causing them to fire prematurely. This last event is thought to contribute to urinary urgency and UUI. The concept of mid-urethral tension-free sling procedures to treat symptomatic SUI was largely based on treating the anatomic deficiencies proposed by Petros and Ulmsten (1990) in their discussion of the integral theory.

Intrinsic Sphincteric Deficiency

Despite the breakthrough in understanding urethral anatomy, function, and support, it remained clear that even with extensive pelvic relaxation and urethral hypermobility, some women were completely continent. More importantly, some women with no hypermobility had fairly severe SUI, particularly those with scarred urethras or certain types of neurogenic disease. **The concept of intrinsic sphincteric deficiency (ISD) was introduced in the urologic literature by McGuire and Lytton (1978) in their initial description of the use of autologous fascial slings for patients with SUI resulting from absent or poor urethral function,** typically secondary to previous urethral surgeries. In this landmark article, the authors noted significant improvements in the majority of patients with severe urethral dysfunction (diagnosed urodynamically) treated by pubovaginal sling, without apparent obstruction in early assessment. Blaivas and Olsson (1988) further characterized ISD later as type III UI to distinguish it from forms of incontinence involving urethral mobility. ISD implies the sphincter activity is dysfunctional, whether because of a neural or a structural problem. Patients with ISD have classically been described as having a “pipestem” urethra, meaning a fixed urethra with little intrinsic closure function. This finding may result from previous surgery and is typically iatrogenic in some way. **Subtler forms of ISD, which typically coexist with the finding of urethral hypermobility, are more commonly found and are likely responsible for most forms of SUI.** ISD in this setting may be secondary to ischemic injury (birth or other trauma) or other forms of progressive pudendal nerve damage.

ISD was historically identified urodynamically using the concept of

Valsalva leak point pressure (VLPP) (McGuire et al., 1996). VLPP testing describes the abdominal pressure required to cause urethral incontinence. VLPP measurement cannot be made in the presence of a detrusor contraction or altered bladder compliance. Low VLPP (less than 60 cm H_2O) has been associated with ISD, and this has been used in the past to direct specific treatments for ISD, such as bulking agents or pubovaginal sling. Both of these treatments may address sphincteric abnormalities and thus were presumed to be more appropriate treatment selections for patients without hypermobility. Our current understanding is that most forms of SUI likely involve some degree of ISD, even if urethral hypermobility is present. This fact underlies the finding that even among patients with hypermobility, treatments such as pubovaginal sling, mid-urethral sling, and even bulking agents appear to have reasonable efficacy (Blaivas et al., 2011; ter Meulen et al., 2009). It is clear, however, that the converse is untrue: that treatments aimed specifically at the correction of hypermobility may be less helpful in the presence of severe ISD and limited mobility. It is for this reason that Burch colposuspension and various needle suspension procedures, for example, have limited usefulness in the treatment of ISD, particularly in the setting of a fixed urethra.

Key Points: Theories on the Pathophysiology of Stress Urinary Incontinence in Women

- **Pressure transmission theory** proposes that descent of the urethra from its protected intraperitoneal position increases the forces placed on more distal urethral continence mechanisms and promotes SUI. Supported by Enhorning (1961) and others, these theories contend that the proximal urethra functionally becomes contiguous with the bladder and, as such, transmission of intra-abdominal forces is placed directly on the urethra. More distal sphincteric mechanisms may not adequately protect against incontinence.
- **Hammock hypothesis**, proposed by **DeLancey** (1994), suggests that the urethra is not truly in an intraperitoneal position, rather that firm posterior and lateral support allows compression of the urethra at times of increased intra-abdominal pressure, when combined with active mid-urethral sphincteric mechanisms. Loss of this support permits the development of

SUI. This theory combines elements of previous theories on urethral hypermobility into a more cohesive, anatomically based explanation.

- **Integral theory,** proposed by Petros and Ulmsten (1990), suggests that UI and SUI are caused by laxity in the vaginal wall and/or surrounding structures (such as pubourethral ligaments). Stretch receptors in the bladder neck, activated at times of increased abdominal pressure with urine deposition in the proximal urethra/bladder neck, are proposed to contribute to urgency incontinence.

Pathophysiology of Insensible Incontinence

Although in most instances women will be able to discern when urine loss occurs, in other cases the timing of incontinence may be unclear. Particularly when incontinence cannot be demonstrated on examination, or cannot be discerned from a thorough history, urodynamic studies and other diagnostic tests may help to determine the cause of leakage. In most cases, the common types of incontinence will still be responsible even if urine loss is insensible, such as sphincteric deficiency or detrusor overactivity incontinence. Other less common causes, however, must be considered, particularly when standard nonoperative measures fail to improve the symptom. Other causes such as urethral diverticula (typically postvoid urine loss), ectopic ureter (typically continuous urine loss), and overflow incontinence (typically small-volume frequent urine loss, urinary frequency, and small volume voids) should be considered. Although urodynamics should identify overflow incontinence, it may miss the other sources, and it may be nondiagnostic in a relatively frequent number of cases (Brucker et al., 2013). Thus in unique circumstances, pelvic MRI (to identify suspected urethral diverticula) and upper tract studies (to identify ureteral ectopy) should be considered in the evaluation of women with insensible urine loss.

Pelvic Floor Support Mechanism

Anatomic support of the pelvic organs in women is provided by endopelvic fascia, the perineal membrane, the levator ani muscle complex, and their attachments to the bony pelvis. **The levator ani muscle complex consists of the pubococcygeus, puborectalis, and iliococcygeus muscles.** It provides the primary support to the pelvic organs, providing a stable base upon which the pelvic organs rest. The opening between the opening of the levator ani muscles through which the urethra, vagina, and rectum pass is the levator hiatus. The endopelvic fascial attachments, in particular the condensations of the endopelvic fascia referred to as the uterosacral and cardinal ligaments, stabilize the pelvic organs in the correct position so that the pelvic muscles can provide optimal support. POP can occur when there is disruption or dysfunction of one or some of these structures.

The normal support of the vagina has been separated into three levels based on cadaveric dissections by DeLancey (1992) (Fig. 115.11). Level I represents the cervix and the upper third of the vagina, level II is the midportion of the vagina, and level III is the most caudal region of the vagina.

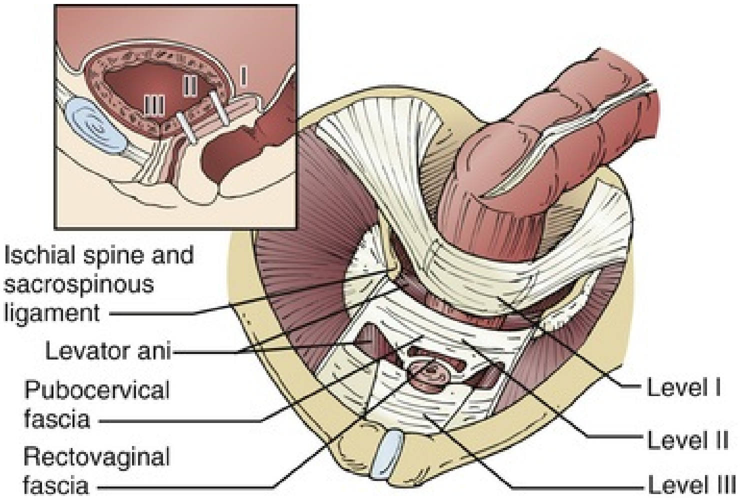

FIG. 115.11 Levels of support, as described by DeLancey (1992). In level I, the paracolpium suspends the vagina from the lateral pelvic walls. In level II, the vagina is attached to the arcus tendineus of the pelvic fascia and superior fascia of the levator ani muscles. The vagina's lower third fuses with the perineal membrane, levator ani muscles, and perineal body (level III).

Level I support suspends the uterus and upper vagina to the sacrum and lateral pelvic sidewall. Level I is composed of the parametrium and the paracolpium, which is the portion of the endopelvic fascia extending from the uterine arteries at its cephalic margin to the point wherever the vagina fuses with the levator ani muscles below. The portion of the endopelvic fascia that attaches the uterus to the pelvis side wall is the parametrium and the portion that attaches to the vagina is the paracolpium. The uterosacral ligament and cardinal ligament complex forms the parametrium and supports the upper third of the vagina and the uterus. The paracolpium is a long sheet of tissue that suspends the superior portion of the vagina by attaching it to the pelvic wall. The uterosacral ligaments are important components of this support. Loss of level I contributes to the prolapse of the uterus or vaginal apex. According to DeLancey, the paracolpium's vertical fibers in level I form the critical factor that differentiates vaginal eversion from posthysterectomy cystocele, rectocele, or enterocele in which the vaginal apex remains well suspended. **Level II** support includes the paravaginal attachments of the middle third of the vagina laterally to the superior fascia of the levator ani muscle and the arcus tendineus fascia pelvis (Fig. 115.12). At that level, the paracolpium changes configuration to form a more direct lateral attachment of the midportion of the vagina to the pelvic wall. The arcus tendineus fascia pelvis is a band of connective tissue attached at one end to the lower sixth of the pubic bone, 1 cm lateral to the midline, and at the other end, just above the ischial spine. Loss of level II support contributes to anterior vaginal wall prolapse. Anterior vaginal wall prolapse can occur either because of a lateral detachment of the paravaginal fascia, referred as **lateral defect**, or a weakness in the midline perivesical fascia, referred as **central defect**. The role of lateral detachment in the development of cystocele was first well established by Richardson et al. (1981). They observed that the most frequently encountered defect in patients undergoing surgery for cystocele was a detachment of the arcus tendineus fascia pelvis from the ischial spine, and rarely from the pubic bone. The posterior aspect of level II connects the midposterior vagina to the inside of the levator ani muscles by sheets of endopelvic fascia.

FIG. 115.12 The cardinal and uterosacral ligaments provide support to the cervix and indirectly to the bladder base. The retropubic, vesicovaginal, and rectovaginal spaces are seen at the level of the cervix. (Modified from Raz S, Stothers L, Chopra A: Vaginal reconstructive surgery for incontinence and prolapse. In Walsh PC, Retik AB, Vaughan Jr ED, et al., editors: *Campbell's urology,* ed 7, Philadelphia, 1998, Saunders, pp 1059–1094.)

Level III is the distal vagina. At that level, the vagina's lower third fuses anteriorly with the urethra, posteriorly with the perineal body, and laterally with the levator ani muscle (superficial and deep perineal muscles). Below the levator ani muscles lies the perineal membrane, which is a layer of connective tissue that attaches the urethra, vagina, and perineal body to the ischiopubic rami. The fibers of the perineal membrane connect to the perineal body, providing a layer of support to prevent downward descent of the rectum. Loss of level III support anteriorly results in urethral hypermobility, whereas loss of posterior level III support results in a distal rectocele or perineal descent.

This classification may oversimplify the pathophysiology of prolapse. The loss of one level of support rarely occurs in isolation. It has become clear that isolated cystoceles or rectoceles are rare and a component of apical prolapse is almost always present (Elliott et al., 2013; Rooney et al., 2006). **The loss of apical support (level I) is highly correlated with the development of anterior prolapse and correlated moderately with the development of posterior prolapse. Therefore the identification of apical prolapse (loss of level I support) is crucial in optimizing the management of prolapse.**

Pathophysiology of Pelvic Organ Prolapse

The levator ani muscle complex is an important component of the pelvic organ support. The opening between the opening of the levator ani muscles through which the urethra, vagina, and rectum pass is referred as the levator hiatus. The portion of the levator hiatus that is situated ventral to the perineal body is the urogenital hiatus. It is through this last hiatus that prolapse of the vagina, uterus, bladder, and rectum occurs. The urogenital hiatus is kept closed by the tonic activity of the levator muscles, which compresses the urethra, vagina, and rectum against the pubic bone and therefore closes the lumen of the vagina.

In the event of direct muscle trauma or denervation, the levator ani muscle tone may decrease, which leads to enlargement of the urogenital hiatus and resultant prolapse (DeLancey, 2005; Singh et al., 2003). This widening of the urogenital hiatus also worsens as the prolapse progresses (Singh et al., 2003). Trauma to the levator ani muscles is most commonly a result of childbirth. On MR imaging, up to 20% of primiparous women have been noted to have visible defects in the levator ani muscle complex, defects that are not seen in nulliparous women. **This suggests that vaginal delivery contributes to POP through levator ani muscle injury** (DeLancey et al., 2003).

Pelvic organ support strongly depends on the interaction between the levator ani muscles and the endopelvic fascia. As long as the urogenital hiatus is kept closed by the levator muscles’ tone, the endopelvic fascia provide little support to the pelvic organ. However, once the organs are unsupported by the levator muscles, the entire support for the pelvic organs has to be provided by the ligaments of the endopelvic fascia. After a period of time, these ligaments tend to fail and prolapse ensues. Injury or stretching of these ligaments can occur during vaginal delivery, hysterectomy, chronic straining, or with normal aging (DeLancey, 2005). There seems to be consistent evidence that collagen metabolism is significantly altered in women with prolapse, which may underlie the failure of these ligamentous attachments. It is also possible that an alteration in the ratio of collagen type I and III could lead to pelvic floor dysfunction (Jackson et al., 1996; Moalli et al., 2005). Whether this alteration is the cause or effect of pelvic organ prolapse remains unclear. However, it is clear that connective tissue disorders have been linked to the development of POP;

patients with Ehlers-Danlos or Marfan syndrome are at enhanced risk of POP (Carley and Schaffer, 2000), supporting the etiologic role of connective tissue disorders as a factor in the pathogenesis of POP.

POP can also result from neuropathic injury. There are two main nerve supplies to the pelvic floor. The pudendal nerve supplies the urethral and anal sphincters and perineal muscles. The nerves to the levator muscles, which originate from S3 to S5 nerve roots, innervate the main musculature of the pelvic floor. Pelvic floor nerve injury probably occurs during vaginal delivery. Weidner et al. (2006) performed electromyography of the levator ani muscles of 58 primiparous women antepartum, at 6 weeks and 6 months after delivery. They found evidence of neuropathy in 24% of woman at 6 weeks and 29% at 6 months. Almost no injury was seen in patients who had undergone elective cesarean sections. Similar levator ani dysfunction was also found in women with cesarean section after labor.

Key Points: Pelvic Floor Support Mechanism and Pathophysiology of Pelvic Organ Prolapse

- The endopelvic fascia, the perineal member, the levator ani muscle complex, and their attachments to the bony pelvis provide the support of the pelvic organs.
- Level I support suspends the uterus and upper vagina to the sacrum and lateral pelvic sidewall. The loss of level I results in uterine and vaginal apical prolapse.
- Level II support provides the support of the middle third of the vagina. Loss of level II support contributes to anterior vaginal wall prolapse.
- Level III support represents the distal vagina. Loss of level III results in urethral hypermobility, distal rectocele, or perineal descent.
- The cause of POP is multifactorial and involves a combination of direct muscle trauma, muscle denervation, and injury or stretching of the endopelvic fascia.

Neuromuscular Dysfunction of the Lower Urinary Tract

Casey G. Kowalik MD, Alan J. Wein MD, PhD (Hon), FACS, Roger R. Dmochowski MD, MMHC, FACS

Objectives

The first part of this chapter is a summary of the abnormalities of the micturition cycle produced by different types of neuromuscular disease, injury, or dysfunction. The background material for the central and peripheral factors involved in the pathophysiology and pharmacology of lower urinary tract (LUT) function are discussed in Chapter 111. An understanding of the physiology and pharmacology of normal urinary storage and emptying, as well as the patterns and location of neuropathic insults, will usually, but not always, enable clinicians to easily infer the associated lower tract dysfunction. The second part of the chapter summarizes secondary factors that can modify the type of observed LUT dysfunction. These secondary factors are important to consider because they cause persistence of storage and voiding abnormalities, even after the initial precipitating factors have resolved or have been corrected. The third part of the chapter describes in detail the specific types of LUT dysfunction that occur secondary to the most common categories of neuromuscular disease, injury, or dysfunction. Ideally, in any such discussion, the expected states of the following urodynamic parameters should be described (see Chapter 115 for specific definitions of terms) (Abrams et al., 2003):

- Sensation (normal, absent, impaired)
- Detrusor activity (normal, overactive, areflexic, impaired contractility)
- Detrusor compliance (normal, decreased, increased)
- Smooth sphincter activity (synergic, dyssynergic)
- Striated sphincter activity (synergic, dyssynergic, bradykinetic, impaired voluntary control, fixed tone)

Table 116.1 is a summary of many of these dysfunctions, grouped by the status of the aforementioned urodynamic parameters and the most common type of abnormal pattern resulting from a given disease or injury. This abbreviated classification is not meant to be all-inclusive but to simply indicate that, for the most part, an individual with a specific neurologic abnormality and subsequent LUT dysfunction will typically have the type of dysfunction listed.

TABLE 116.1

Most Common Patterns of Voiding Dysfunction Seen With Various Types of Neurologic Disease or Injury[a]

Compliance: *N,* normal; ↓, decreased; ↑, increased.

Detrusor activity: *A,* areflexia; *I,* impaired; *Ov,* overactive.

Smooth sphincter: *CNR,* competent, nonrelaxing; *D,* dyssynergic; *Op,* open, incompetent at rest; *S,* synergic.

Striated sphincter: *D,* dyssynergic; *F,* fixed tone; *S,* synergic; ±*VC,* voluntary control may be impaired.

The chapter concludes with a general consideration of the principles that should guide the selection of therapeutic interventions for the types of neuromuscular dysfunctions considered. Other chapters cover in detail the individual therapies and their potential consequences, as well as the types of LUT dysfunction in the pediatric age group and their management.

Patterns of Neuropathic Voiding Dysfunction

In general, discrete neurologic lesions affect the filling and storage and the emptying and voiding phases of LUT function in a relatively consistent manner. This nature of the impact is dependent on (1) the area(s) of the nervous system affected; (2) the physiologic function(s) and the contents and location of the area(s) affected; and (3) whether the lesion or process is destructive, inflammatory, or irritative. The acute dysfunction produced may, for a variety of reasons, be different from the chronic one.

Neuroplasticity

As it relates to the nervous system and the structures it innervates, ***plasticity*** **is the inherent capacity to undergo structural and functional modification.** These induced changes can be reflected on a number of levels: structural, metabolic, and neurologic. In addition, the neurologic changes can then be reflected on a number of levels: morphologic, neurochemical, electrical, and organizational. Each of these changes can be studied at a variety of different levels, from investigation of the end product (e.g., the clinical manifestations) to exploration of the initial molecular correlates and the factors that induce or affect them. The chronic clinical manifestations that we associate with a particular voiding dysfunction may be the ultimate results of the phenomena that fall under the rubric “plasticity.” Up to a certain point the changes may be reversible, but after a certain point they may not be. Thus **plasticity may account for the persistence of clinical symptoms after the initial stimulus.**

Perhaps the most obvious changes that occur as a result of plasticity are (1) chronic changes in neural organization of the micturition reflex that occur after complete spinal cord transection above the cord level of S2 and (2) the changes in peripheral neural organization that occur after damage to or transection of the peripheral parasympathetic innervation of the LUT. Specific details are contained in the relevant sections of this chapter.

Perhaps the less obvious results of plasticity are many of the changes that occur subsequent to bladder outlet obstruction. The most obvious changes that occur are those related to muscle and collagen content. However, these are initiated by molecular events that ultimately cause increased contractile protein synthesis and hypertrophic bladder tissue growth (Levin et al., 1995). The initial stimulus may be stretch from overdistention (Cheng et al., 1999) or ischemia, likewise from distention (Chen et al., 1996). Compensation of the bladder smooth muscle cells to initially overcome the increased demand associated with obstruction is associated with alterations in the expression and function of many proteins involved in excitation-contraction coupling and active force generation of bladder smooth muscle (Chacko et al., 1999). Although urodynamic studies reflect obstruction, satisfactory emptying is usually preserved. Changes in the composition of the extracellular matrix occur as well, presumably also caused by an initial stretch stimulus. The ratio of type III collagen to type I collagen increases, and the localization of type III collagen changes as well (within some muscle bundles as well as around them) (Macarak and Howard, 1999). The increase in connective tissue could be related to an increase in certain growth factors emanating from the smooth muscle or to a decrease in the activity of certain metabolic pathways contributing to the breakdown of various forms of collagen (Borer et al., 1999). Ischemia, which can be caused by obstruction or by atherosclerosis, has also been hypothesized to contribute to remodeling of the extracellular matrix and fibrosis (Azadzoi et al., 1999; Mostwin et al., 2005).

Bladder outlet obstruction has a suggested association with partial denervation because of damage to the intrinsic innervation of the bladder smooth muscle from a combination of pressure and ischemia (Mostwin et al., 2005; Turner and Brading, 1997). With all of these potential adverse changes occurring, it seems almost miraculous that the bladder is able to maintain its function, but it does for variable periods of time under different circumstances. However, there does come a point at which the ability to fill and store and empty is adversely affected, but not necessarily to the same extent. Filling and storage changes seem related primarily to (1) changes in the extracellular matrix, leading to decreased compliance, and (2) the appearance of phasic bladder overactivity. This overactivity could be myogenic (caused by partial denervation [Turner and Brading, 1997]), or it could be neurogenic and related to another facet of plasticity. Afferent neuroplasticity mediated by nerve growth factors (NGFs) occurs experimentally in response to bladder outlet obstruction, a phenomenon that is inhibited by autoimmunization against NGF (Steers et al., 1996). The ability to empty can be adversely affected by factors related to neurogenic or myogenic mechanisms. The myogenic mechanisms could include a reversal of the compensatory changes that initially occur (see Chacko et al., 1999) or a breakdown of the structure and function of the proteins that enable the smooth muscle cells to take up, store, and release calcium, affecting the calcium activation of the contractile apparatus (Chacko et al., 1999; Zderic et al., 1998).

Furthermore, these neurogenic changes associated with outflow obstruction may alter the neurotransmitter milieu of the LUT. In a model of fetal sheep bladder outlet obstruction, ligation of the urachus at mid-gestation in fetal sheep for 1 month resulted in a shifting of muscarinic, purinergic, and nitrergic mechanisms normally present during fetal development and growth. With outflow obstruction, bladder hypocontractility was induced and contractile forces decreased during stimulated conditions, consistent with denervation and the possibility of atropine resistance. Normal urothelial exerted negative ionotropic effects (nitric oxide mediated) were also lost after obstruction. In addition, loss of compliance resulted in reduced elasticity in the obstructed bladders, consistent with denervation (Thiruchelvam et al., 2003). At this time, certain precipitating factors for the initiation of LUT dysfunction cannot be reversed, such as spinal cord transection and peripheral nerve injury. Therefore the fact that the changes that result from the neuroplasticity induced by these insults are permanent is not surprising. However, **there are instances in which the initiating "cause" of a particular voiding dysfunction can be removed and yet the symptoms do not entirely disappear. This may be another instance in which neuroplasticity is a major factor.** For instance, irritative lower urinary tract symptoms (LUTS) fail to disappear in a certain percentage of patients with outlet obstruction who undergo surgical correction. Chai et al. (1998) found an increased incidence of a positive ice-water test result in patients with bladder outlet obstruction, indicating the presence of a primitive reflex circuitry capable of mediating an abnormal micturition reflex. Because the ice-water test is mediated by C-afferent fibers, the findings support the hypothesis that bladder outlet obstruction is associated with afferent neuroplasticity, detectable in this case by ice-water cystometry. Furthermore, persistence of this afferent neural plasticity after relief of the obstruction could account for at least a proportion of the symptomatic treatment failures after urodynamically successful outlet reduction. A bladder outlet obstruction animal model demonstrated normalization of bladder function and gene expression profiles after de-obstruction in those animals who had detrusor overactivity before de-obstruction (Lee et al., 2017b). Specifically, de-obstructed rats with detrusor overactivity and bladder outlet obstruction had lower expression levels of cyclin-dependent kinase inhibitor 1A, zinc finger protein 162, and vascular endothelial growth factor A (more closely resembling a normal bladder) than those rats without detrusor overactivity and bladder outlet obstruction. These data suggest that detrusor overactivity in response to bladder outlet obstruction not only may be an adaptive process to ensure bladder emptying but also exhibits the plasticity of the bladder to diseased and treated states.

Vizzard (1999, 2000a, 2000b, 2000c, 2000d) and Qiao and Vizzard (2004) have written prolifically about various aspects of neuroplasticity, specifically on the occurrence and potential role of such changes in altered LUT dysfunction after spinal cord injury (SCI) and irritant-induced cystitis. Changes in spinal cord protein expression from bladder neurotrophic factors transported retrograde could play a role in the neurochemical, electrophysiologic, and organizational properties of the LUT seen in both of these conditions and could account, in the latter case, for persistence of symptomatic and/or urodynamic abnormalities after the irritating stimulus has been removed (e.g., in patients with interstitial cystitis).

Diseases at or Above the Brainstem

Cerebrovascular Disease

Cerebrovascular Accident (Stroke)

Cerebrovascular accident (CVA) is a common cause of death and one of the most common causes of disability in the world. CVA is the most devastating manifestation of cerebrovascular disease, with an **annual incidence in the United States that has been cited as more than 795,000** (https://www.cdc.gov/stroke) **and 15 million worldwide** (www.strokecenter.org). The prevalence of stroke in persons older than 65 years has been cited as approximately 60 in 1000, and in persons 75 years of age and older, 95 per 1000 (Khan et al., 1990; Public health and aging, 2003). Wyndaele et al. (2005, 2009) estimated that 1 in 200 individuals will sustain a CVA. Although CVA is the fifth leading cause of death in the United States (https://www.cdc.gov/stroke), approximately 75% of stroke victims survive (Addo et al., 2012), often with post-stroke sequelae, such as impaired mobility, changes in cognitive function, and urinary urgency, frequency, and incontinence.

Thrombosis, occlusion, and hemorrhage are the most common causes of stroke leading to ischemia and infarction of variably sized areas in the brain, usually around the internal capsule, but with the potential to affect areas responsible for coordinated voiding. Strokes most commonly affect the elderly; therefore the presentation and management of these patients are more complex because of preexistent LUT pathology and other comorbidities that may affect the LUT. Although the urinary symptoms may have been manageable before the CVA, they may become significantly worse afterward. Also, other deficits after CVA can affect general rehabilitation and control of the LUT dysfunction. These may include cognitive impairment, dysphasia, inappropriate and aggressive behavior, impaired mobility, and low motivation, complicating management of the urinary symptoms.

The exact acute and chronic incidence of any voiding dysfunction after CVA is difficult to determine, but **the cited prevalence of urinary incontinence ranges from 32% to 79% on hospital admission for CVA, 25% to 28% on discharge, and 12% to 19% several months** later (Brittain et al., 1998). Fowler (1999) cited studies showing that the presence of urinary incontinence within 7 days of a stroke is a more powerful prognostic indicator for poor survival and functional dependence than a depressed level of consciousness. Gariballa (2003) found that urinary incontinence at admission had a hazard ratio of 2.8 as a predictor of death from CVA at 3 months. Stroke patients who were incontinent had an increased risk of infectious complications and were malnourished, possible confounders of the increased death risk. Patel et al. (2001) reported that urinary incontinence was associated with age older than 75 years, dysphagia, visual field defect, and motor weakness.

Certain specific types of strokes also appear to be associated with unusual forms of incontinence. Lenticulocapsular strokes have been noted to be associated with incontinence. Fifty-two percent of patients with strokes in this area of the brain demonstrated post-stroke emotional incontinence, which was not related to other aspects of stroke or gender (Kim, 2002). The prevalence of urinary and fecal incontinence after hemispheric vascular accident has ranged from 21% to 56% in earlier studies. Urinary incontinence associated with fecal incontinence is the most prevalent condition on admission to rehabilitation units after a vascular event, being prevalent in approximately 33% of patients. Isolated urinary incontinence follows at a rate of 12% and finally isolated fecal incontinence with 8%. The most prevalent form of urinary incontinence is impaired awareness (insensate or delayed awareness of voiding events), occurring in 12% to 58% of individuals, as compared with pure urge, which occurs in 9% to 42%. This impaired awareness incontinence is a more significant negative prognostic indicator for resolution of symptoms as compared with patients who retain the sensation of urgency (Kovindha et al., 2010; McKenzie and Badlani, 2012).

After an acute CVA, urinary retention from detrusor areflexia often occurs because of “cerebral shock”; however, the neurophysiology of this “cerebral shock” is unclear. After a variable degree of recovery from the neurologic insult, a fixed deficit may become apparent over a few weeks or months. **The most common LUT dysfunction after CVA is phasic detrusor overactivity** (Fowler, 1999; Khan et al., 1990; Wein and Barrett, 1988; Wyndaele et al., 2005). Recall that detrusor overactivity is the urodynamic observation of an involuntary detrusor contraction during filling. **Sensation is variable but most typically intact, and thus the patient experiences urinary urgency and frequency with detrusor overactivity. In response to the detrusor overactivity, the patient may try to voluntarily and forcefully contract the striated sphincter to prevent leakage. If this can be accomplished, only urgency and frequency result; if not, then urge urinary**

incontinence occurs.

In addition, the LUT dysfunction may be significantly and adversely affected by treatment regimens that concentrate on detrusor overactivity alone (e.g., anticholinergic or antispasmodic therapy). Vigorous pharmacologic therapy of detrusor overactivity with agents that cross the blood-brain barrier and inhibit M_1 muscarinic receptors may worsen preexisting confusion, disorientation, and other problems of mentation in these patients.

In a nationwide Danish assessment of patients after an acute stroke, at 1 month after the stroke, patients were asked to assess the severity of their urinary symptoms as well as bother related to each symptom. A total of 482 eligible patients were assessed; 94% of patients had had at least one urinary symptom in the prior 2 weeks, with nocturia being the most frequent (76%), followed by urgency (70%) and urinary daytime frequency (59%). Urgency was the symptom associated with the most bother, followed by nocturia and finally frequency. If a patient had at least one symptom, bother was at least 78%. Bother caused by urinary symptoms was associated with severity of lower extremity paresis, as well as use of analgesics. The overall conclusion was that LUTS were highly prevalent and also had significant impact on overall bother in this population (Tibaek et al., 2008).

Previous descriptions of LUT dysfunction patterns after CVA have overwhelmingly cited detrusor overactivity with coordinated striated and smooth sphincter activity (Drake et al., 2013; Kolominsky-Rabas et al., 2003; Wyndaele et al., 2005). **It is difficult to reconcile this with the relatively high rates of urinary incontinence in these patients, despite the probability that a percentage of these patients already had an incontinence problem before the CVA.** Tsuchida et al. (1983) and Khan et al. (1990) made early significant contributions in this area by correlating the urodynamic and computed tomographic (CT) pictures after CVA. They concluded that patients with lesions in only the basal ganglia or thalamus have normal sphincter function. This indicates that these patients could voluntarily contract the striated sphincter and abort or minimize the effect of an abnormal micturition reflex when an impending involuntary contraction was sensed. Most patients with involvement of the cerebral cortex, internal capsule, or both were unable to forcefully contract the striated sphincter under these circumstances. Although the authors and others have called this problem “uninhibited relaxation of the sphincter” (Marinkovic and Badlani, 2001), this term is a misnomer. In actuality, the term implies that a profound abnormality exists in the cerebral to corticospinal circuitry that is necessary for voluntary control of the striated sphincter. In an assessment of 192 stroke patients, of whom 69 had undergone urodynamic evaluation, minor urodynamic differences were noted among patients with strokes in the dominant versus nondominant hemisphere versus bilateral hemispheric strokes. Of the dominant hemispheric stroke patients, 64.2% demonstrated detrusor overactivity; detrusor underactivity was present in 35% of the patients. In contradistinction, nondominant hemispheric stroke resulted in detrusor overactivity in 66% of patients and detrusor underactivity in 33%, whereas of bilateral stroke patients, 60% demonstrated detrusor overactivity and 40% detrusor underactivity. Therefore no significant difference was noted between location of stroke and urodynamic findings (Kim et al., 2010).

Thus there are two possible mechanisms for the incontinence associated with involuntary bladder contractions in patients who have sustained a CVA: (1) impaired striated sphincter control and (2) lack of appreciation of bladder filling and impending bladder contraction. In general, the smooth sphincter is unaffected after CVA and remains synergic. Some authors describe striated sphincter dyssynergia in 5% to 21% of patients who manifest brain disease and voiding dysfunction (Sakakibara et al., 1999); however, this appears to be incompatible with accepted neural circuitry. **True detrusor striated sphincter dyssynergia does not occur in this situation, although pseudodyssynergia has been found to occur** during urodynamic testing of these patients (Wein and Barrett, 1982). This finding refers to an electromyographic sphincter “flare” during filling cystometry that is secondary to attempted inhibition of an involuntary bladder contraction by voluntary contraction of the striated sphincter. The guarding reflex in these patients usually remains intact (Siroky and Krane, 1982).

Detrusor hypocontractility or areflexia may rarely persist after CVA. The exact incidence of areflexia as a cause of chronic voiding symptoms after CVA is uncertain, but some estimates place it as high as 20% (Arunable and Badlani, 1993). Patients with urinary retention after CVA generally have not only poor functional status in the rehabilitation period but also poorer recovery (Son et al., 2017). Linsenmeyer and Zorowitz (1992) found that 35% of men who were incontinent after a CVA had involuntary bladder contractions with urodynamic evidence of bladder outlet obstruction and 6% had detrusor areflexia. In comparison, 13% of women in this group had involuntary contraction with a large residual urine volume and 19% had areflexia. **Poor flow rates and high residual urine volumes in a man with LUTS before CVA usually indicate**

prostatic obstruction. However, a full urodynamic evaluation to exclude detrusor overactivity with impaired contractility as a cause of symptoms is advisable before committing such a patient to surgical reduction of bladder outlet obstruction.

The underlying basic mechanisms of bladder overactivity after CVA remain unclear. Experimental models of middle cerebral artery occlusion have been described, followed by reperfusion to simulate the clinical condition (Pehrson et al., 2003). Shimizu et al. (2003) described the development of a rat model involving an electrolytic lesion of the right basal forebrain. After middle cerebral artery occlusion, neural signaling changes seem to involve glutaminergic, dopaminergic, and γ-aminobutyric acid (GABA)-ergic mechanisms (Kanie et al., 2000; Yokoyama et al., 2002). In addition, Fu et al. (2004) have shown upregulation of proinflammatory cytokines and the neuronal nitric oxide synthase gene in the spinal cord and bladder after acute vascular injury. Such findings raise interesting theoretic possibilities for central pharmacologic management. Cerebrovascular injury manifesting with suprapontine injury also can result in an alteration of urinary urgency perception, producing symptomatic frequency and urge incontinence. The underlying pathophysiology of this effect may be elimination of cortical ambulatory control of the pontine micturition center (PMC), possibly combined with facilitation of excitatory control. These aberrant signaling pathways may arise from abnormalities in acetylcholine, dopamine, and glutamate regulatory changes with upregulation or downregulation of excitatory and inhibitory pathways resulting in the overactivity associated with diagnosis (Yokoyama et al., 2009).

Brainstem Stroke

The brainstem includes the midbrain, the pons, and the medulla oblongata. The PMC is involved in suprapsinal coordination of micturition and is located in the pons. In another study of 39 patients with acute brainstem stroke (Sakakibara et al., 1996d), the primary complaints were nocturnal frequency and voiding difficulty in 6, urinary retention in 8, and urinary incontinence in 3. Symptoms did not occur in those with strictly midbrain lesions but occurred in 18% of patients with medullary stroke and in 35% of patients with pontine lesions. Detrusor overactivity was found in 8 of the 11 symptomatic patients who underwent urodynamic evaluation, and low compliance was found in 1 patient.

Yum et al. (2013) reported on 30 patients who underwent urodynamic evaluation after a brainstem stroke. No patients had pre-stroke urinary symptoms. Fourteen (46%) were found to have a low bladder capacity, which was more common in those with a pontine infarction, and 7 (23%) had a bladder emptying disorder, which was more common in patients with a medullary infarction.

In a study of 20 patients with brainstem stroke (14 with pontine stroke and 4 with medullary stroke) by Lee et al. (2017a), urodynamic studies most commonly showed detrusor underactivity in 11 out of 14 with pontine stroke and 1 out of 4 with medullary stroke. These studies demonstrate that different patterns of voiding dysfunction can be associated with locations of brainstem stroke and that pontine lesions can disrupt pathways of coordinated voiding; however, stroke location cannot always predict findings, and complete evaluation with urodynamic studies is prudent.

Dementia

Dementia is a poorly understood disease complex involving atrophy and the loss of gray and white matter of the brain, especially in the frontal lobes, causing deficits with memory and the performance of tasks requiring intellectual mentation. Associated conditions include widespread vascular disease, Alzheimer disease, Pick disease, Creutzfeldt-Jakob disease, syphilis, traumatic brain injury, and encephalitis. Alzheimer disease is the principal cause of dementia in the elderly (Drake et al., 2013; Wyndaele et al., 2005). **Although urinary dysfunction does not consistently accompany dementia, when voiding dysfunction occurs the result is typically incontinence. It is difficult to ascertain whether the pathophysiology and considerations are similar to those in the stroke patient or whether the incontinence reflects a situation in which the individual has simply lost the awareness of the desirability of voluntary urinary control.** Even if the person has voluntary sphincter control, such individuals may void when and where they please, because impaired mentation fails to dictate why they should not. Such activity may be caused by detrusor overactivity or an otherwise normal, but inappropriately timed, micturition reflex. An accurate estimate of the prevalence of dementia-associated incontinence is confounded by the difficulty in distinguishing this from age-related changes in the bladder and from other concomitant diseases, as pointed out by Wyndaele et al. (2005) and Drake et al. (2013), who cite figures of 30% to 100%. Prevalence may be also difficult to establish because patients with dementia may not be aware of incontinence as highlighted in this study by Cohn et al. (2017), who found only moderate agreement between patient-reported incontinence and nurse-reported incontinence in geriatric inpatients. Treatment can be difficult and the outcomes frustrating without a desire for improvement. Medical therapy for incontinence generally involves the use of anticholinergic medications, which are associated with worsening cognitive impairment, delirium, and falls (Saraf et al., 2017). One theory on the cause of Alzheimer disease is cortical cholinergic loss, thus use of anticholinergics can further exacerbate symptoms.

Traumatic Brain Injury

Traumatic brain injury has been cited as the most common form of severe neurologic impairment resulting from trauma (Blaivas and Chancellor, 1995a). **As with many neurologic insults, there may be an initial period of detrusor areflexia when LUT dysfunction occurs. With lesions above the PMC, detrusor overactivity and coordinated sphincter function are the most frequent manifestations of chronic LUT dysfunction. In patients who have more isolated brainstem injuries with involvement below the PMC, additional findings may include detrusor striated sphincter dyssynergia.**

Chua et al. (2003) assessed 66 males and 18 females within 6 weeks of acute traumatic brain injury. Of these patients, 62% had urinary incontinence on admission, with urinary retention (defined as postvoid residual volume greater than 100 mL) noted in 9.5%. Sixty-two percent required either indwelling catheters or external collecting devices for urinary maintenance. Urinary incontinence was associated with poor functional status and bilateral lesions, whereas urinary retention was more commonly noted in patients with comorbid diabetes mellitus or fecal impaction. After rehabilitation, 36% remained incontinent. Patients with traumatic brain injury often have concomitant spinal injuries, contributing to the LUT dysfunction and complicating management.

Brain Tumor

Disturbances of bladder function have been associated with primary and metastatic brain tumors. When dysfunction results, it is related to the localized area involved rather than to the tumor type. **The areas most frequently involved with associated micturition dysfunction are the superior aspects of the frontal lobe** (Blaivas, 1985). **When LUT dysfunction occurs, it usually**

consists of detrusor overactivity and urinary incontinence. These individuals may have a markedly diminished awareness of all LUT events and, if so, may be totally unable to even attempt suppression of the micturition reflex. **In general, smooth and striated sphincters are synergic,** whereas pseudodyssynergia may occur during urodynamic testing. In a review of frontal lobe lesions and bladder control, Fowler (1999) cites instances of improvement of micturition symptoms for a period of time after tumor resection, raising the question of whether the phenomenon of tumor-associated bladder overactivity was a positive one (activating some system) rather than a negative one (releasing a system from control). **Urinary retention has also been described** in patients with space-occupying lesions of the frontal cortex, in the absence of other associated neurologic deficits (Lang et al., 1996). Posterior fossa tumors may be associated with voiding dysfunction (32% to 70%, based on references cited by Fowler, 1999). Retention or difficulty voiding is the rule, with incontinence being a rare finding.

Cerebellar Ataxia

Cerebellar ataxia is a group of diseases involving pathologic degeneration of the nervous system, usually involving the cerebellum but with possible extension to the brainstem, spinal cord, and dorsal nerve roots (Leach et al., 1982). Cerebellar involvement often results in poor coordination, depressed deep tendon reflexes (DTRs), dysarthria, dysmetria, and choreiform movements. **LUT dysfunction typically manifests with incontinence, usually associated with detrusor overactivity and sphincter synergy. Retention or high postvoid residual urine volume may occur as well. When present, impaired emptying is most commonly caused by detrusor areflexia, but it may also be associated with detrusor striated sphincter dyssynergia, presumably a result of spinal cord involvement.** Sakakibara et al. (1998b) reported micturition symptoms in 184 patients with spinocerebellar degeneration, of whom 29 (15.8%) had stress urinary incontinence. Although 20 of these 29 also had detrusor overactivity, low compliance, and/or elevated residual urine, the remaining 9 had none of these findings. The authors speculated that, in the absence of other findings, spinal lesions affecting the Onuf nucleus and consequently pudendal nerve function were responsible for the development of stress urinary incontinence.

Normal-Pressure Hydrocephalus

Normal-pressure hydrocephalus (NPH) is a neurologic condition characterized by progressive dementia, ataxia, and urinary incontinence occurring in patients with normal cerebrospinal fluid pressure and distended cerebral ventricles. NPH can be idiopathic or occur after neurologic insults, such as a CVA. The urinary incontinence is secondary to detrusor overactivity with synergic sphincters (Blaivas, 1985; Krzastek et al., 2017a). Cerebrospinal fluid shunting, primarily via a ventriculoperitoneal shunt, is the mainstay of treatment and can result in clinical improvement of urinary symptoms, specifically urinary urgency and urge incontinence (Krzastek et al., 2017b).

Cerebral Palsy

Cerebral palsy (CP) is a nonprogressive injury of the brain that typically occurs during the first year of life (but potentially up to 3 years of age) and produces neuromuscular disability and/or specific symptom complexes of cerebral dysfunction. In general, the cause is infection or a period of hypoxia. Affected children exhibit delayed gross motor development, abnormal motor performance, altered muscle tone, abnormal posture, and exaggerated reflexes. **Most children and adults with only CP have urinary control and what seems to be normal storage and emptying.** The actual incidence of LUT dysfunction in the CP population is unclear, because the few available series report findings predominantly in those with LUTS. Andrews (1994) estimates that a third or more of children with CP have urinary symptoms, whereas Roijen et al. (2001) surveyed children and adolescents from six rehabilitation centers and cited the prevalence of “primary urinary incontinence” as 23.5%. The most important factors influencing the occurrence of incontinence were spastic tetraplegia and low intellectual capacity. Wyndaele et al. (2005) and Drake et al. (2013) cite the occurrence of LUT dysfunction as 36%. Those children who do attain daytime and nighttime continence do so at a higher median age compared with normal controls (Wright et al., 2016a).

Reid and Borzyskowski (1993) described findings in 27 patients (ages 3 to 20 years) who were referred because of LUT dysfunction. Incontinence (74%), urinary frequency (56%), and urgency (37%) were the most common presenting symptoms, and detrusor overactivity was the most common urodynamic abnormality (87% of those undergoing urodynamics), with 25% of these exhibiting apparent striated sphincter dyssynergia. Mayo (1992) reported on 33 CP patients referred for evaluation of micturition dysfunction, of whom 10 were older than 20 years. Difficulty urinating was the predominant symptom in about half the patients, but half of these also had overactivity and urgency when the bladder was full. The cause of the difficulty in voluntarily initiating micturition was thought to be a problem with relaxing the pelvic floor and not true striated sphincter dyssynergia. Incontinence was the major presenting symptom in the other half, with associated detrusor overactivity in 14 of 16. All patients exhibited normal voiding otherwise. Decreased sensation was reported in 17 of 23 patients younger than 20 years of age and in 4 of 10 older than 20. The more serious manifestations, such as retention, were found only in the adults, prompting the authors to suggest that difficulty urinating may progress in adulthood. In another assessment of a children with CP, Richardson and Palmer (2009) evaluated 15 boys and 16 girls with urodynamics. Social continence was highly associated with larger capacity bladder with lower storage pressures (presumably improved compliance), lack of uninhibited contractions, and coordinated (lack of pseudodyssynergia) sphincter activity. Bladder sensation differed substantially in continent versus incontinent patients. The main difference between continent and incontinent groups appeared to be delayed bladder sensation in the incontinent group (Richardson and Palmer, 2009). Cotter et al. (2016) performed urodynamic studies in 49 adults with CP and voiding dysfunction with findings of detrusor overactivity in 30% and detrusor sphincter dyssynergia (DSD) in 12%. Importantly, poor compliance and elevated detrusor leak point pressure above 40 cm H_2O were seen in more than half of patients. **Adults with CP and urinary symptoms should undergo complete evaluation because the rate of bladder dysfunction is high** with risks of renal damage.

In individuals with CP who exhibit significant dysfunction, the type of damage that one would suspect from the most common urodynamic abnormalities seems to be localized anatomically above the brainstem. Therefore this is most commonly reflected by phasic detrusor overactivity and coordinated sphincters. However, spinal cord damage can occur, and perhaps this accounts for those individuals with CP who seem to have evidence of striated sphincter dyssynergia or of a more distal type of neural axis lesion. Reid and Borzyskowski (1993) noted that incontinence can be significantly improved in most CP patients and that, in their experience, intellectual delay is not a barrier to successful management. Goldfarb et al. (2016) found that conservative management, specifically education, incontinence padding, and perineal hygiene, was successful in 75%. In those patients requiring catheterization, initiation of intermittent catheterization was successful in 32%, whereas 39% ultimately underwent surgical reconstruction and the remainder returned to previous voiding patterns. The severe degree of mental delay encountered in some of these individuals makes their management very difficult; any evaluation or treatment that requires cooperation may be impossible.

Parkinson Disease

Parkinson disease (PD) is a neurodegenerative disorder of unknown cause that affects primarily the dopaminergic neurons of the substantia nigra and heterogeneous populations of neurons in other locations (Lang and Lozano, 1998). The most important site of pathology is the substantia nigra pars compacta, the origin of the dopaminergic nigrostriatal tract to the caudate nucleus and putamen. **Dopamine deficiency in the nigrostriatal pathway accounts for most of the classic clinical motor features of PD,** a symptom complex referred to as *parkinsonism*, the major signs of which are tremor, skeletal rigidity, and bradykinesia. Other pathways that may contribute to abnormal neural physiology in PD include the corpus striatum, thalamus, periaqueductal gray matter (PAG), and L and M regions of the PMC, as well as the ventral tegmental area (VTA) of the midbrain (Barbalat, 2010). The role of alterations in dopaminergic receptor subtypes has been assessed in animal models of PD. Treatment with dopamine D_2 agonists and D_1 antagonists appears to result in a reduction of bladder capacity in these models. Brusa et al. (2006) studied a group of 87 patients with mild PD who were evaluated by symptomatic change and urodynamics after administration of selective dopaminergic agents. Use of agents causing central acute D_2 stimulation resulted in a reduction in bladder capacity and worsened detrusor overactivity, as compared with peripheral dopaminergic antagonists (Brusa et al., 2006). Lang and Lozano (1998) compiled an excellent review of conditions causing parkinsonism other than PD and clinical features of these conditions distinguishing them from PD. These other causes of parkinsonism include (1) multiple system atrophy (MSA) (includes striatonigral degeneration, sporadic olivopontocerebellar atrophy, and Shy-Drager syndrome); (2) progressive supranuclear palsy (PSP); (3) cortical-basal ganglionic degeneration; (4) so-called vascular parkinsonism; and (5) Lewy body dementia. **The combination of asymmetry of symptoms and signs, the presence of a resting tremor, and a good response to levodopa best differentiates PD from parkinsonism produced by other causes, although none of these is individually specific for PD** (Fowler, 2007).

Wyndaele et al. (2005) and Drake et al. (2013) endorsed **additional criteria that favor MSA as a cause of LUTS rather than PD: (1) urinary symptoms that precede or occur with onset of parkinsonism; (2) presence of urinary incontinence; (3) significant postvoid residual volume; (4) initial erectile dysfunction; and (5) abnormal striated sphincter electromyographic findings.** In addition, 5% of patients initially diagnosed with PD are found to have Parkinson-plus syndromes, characterized by early dementia and/or falls, symmetrical symptoms, wide-based gait, normal eye movements, autonomic dysfunction, and marked disability. These variants tend to have a worse prognosis than idiopathic PD, and urinary function is not well described in this subgroup of patients (Nutt and Wooten, 2005).

The gold standard for the diagnosis of PD is neuropathological examination. In addition to the characteristic pattern of the loss of selected populations of neurons, there is the presence of degenerating ubiquitin-positive neuronal processes or neurites (Lewy neurites) found in all affected brainstem regions. The Lewy body is an intracytoplasmic eosinophilic hyaline inclusion consistently observed in selectively vulnerable neuronal populations. Lewy bodies are not specific to PD and may be found in small numbers in other neurodegenerative disorders. PD affects both sexes roughly equally, and the prevalence is cited as 0.3% of the general population and 3% of people older than 65 years (Lang and Lazano, 1998).

Depending on the definition, LUT dysfunction occurs in 35% to 70% of patients with PD (Berger et al., 1990; Blaivas et al., 1998a; Sotolongo, 1993; Wein and Rovner, 1999; Wyndaele et al., 2005). Preexisting detrusor dysfunction or bladder outlet abnormalities may be present, and the symptomatology may be affected by various types of treatment for the primary disease. LUTS is a frequent manifestation of PD. The time from onset of PD to initiation of LUTS in most studies averages 5 years. The most frequent symptoms include nocturia in 86% of patients, followed by frequency in 71% of patients and urgency in 68% of patients. It has been hypothesized that dopamine modulates the normal micturition reflex, and therefore neurogenic degeneration in the nigrostriatal pathway leads to the significant LUT dysfunction associated with PD (Campeau et al., 2011). One early manifestation of PD may be deficient perception of sensory information in visceral neuronal pathways resulting in delayed perception of bladder filling. Studies have demonstrated that the deep brain stimulation used for improvement of moving function in patients with PD may also benefit this sensory perception (Herzog et al., 2006).

When LUT dysfunction does occur, 50% to 75% of the time symptoms consist of urgency, frequency, nocturia, and urgency incontinence. The remainder of patients have obstructive symptoms or a combination of storage and voiding symptoms. **The most common urodynamic finding is detrusor overactivity.** The pathophysiology of detrusor overactivity most widely proposed (Fowler, 1999) is that the basal ganglia normally have an inhibitory effect on the micturition reflex, which is abolished by the cell loss in the substantia nigra. It is currently unclear whether the dopamine D_1 or D_2 receptor (or both) is primarily responsible. It has been suggested that loss of inhibitory D_1-like receptors causes detrusor overactivity, allowing D_2 receptors to facilitate micturition (Andersson, 2004). **The smooth sphincter is synergic.** Sporadic involuntary activity in the striated sphincter during involuntary bladder contraction has been reported in as many as 60% of patients; however, this does not cause obstruction and cannot be termed *true* detrusor sphincter dyssynergia (DSD), which in general does not occur.

Pseudodyssynergia may occur, as well as a delay in striated sphincter relaxation (bradykinesia) at the onset of voluntary micturition, both of which can be urodynamically misinterpreted as true dyssynergia. Impaired detrusor contractility may also occur, in the form of low amplitude or poorly sustained contractions or a combination of these. Detrusor areflexia is relatively uncommon in PD. PET revealed changes in nine patients in brain activation associated with detrusor overactivity, specifically in the periaqueductal gray, supplementary motor area, cerebellar vermis, insula, putamen, and thalamus. The most prominent degree of increased activation was noted in the cerebellum, with no change in pons during detrusor overactivity (Kitta et al., 2006).

However, many cases of “PD” in the older literature may actually have been MSA, and citations regarding symptoms and urodynamic findings may therefore not be accurate. A good and important example of this is the inference from the publication by Staskin et al. (1988) that transurethral resection of the prostate (TURP) in the patient with PD is associated with a high incidence of urinary incontinence because of poor striated sphincter control. Retrospective interpretation (Drake et al., 2013; Fowler, 1999, 2001; Wyndaele et al., 2005) has shown that these were patients with MSA and not PD and that **TURP should not be contraindicated in patients with PD, because striated sphincter acontractility is extremely rare** in such patients. However, irrespective of similar studies, one must be cautious with such patients, and a complete urodynamic or videourodynamic evaluation is advisable. Poorly sustained bladder contractions, sometimes with slow sphincter relaxation, should make one less optimistic regarding the results of outlet reduction in the male. In addition, the diagnosis of PD should be confirmed and MSA should be excluded before benign prostatic hypertrophy surgery because sphincter involvement in MSA could lead to florid incontinence after surgery.

LUT dysfunction secondary to PD defies routine classification within any system. It manifests mostly with storage failure secondary to bladder overactivity, but detailed urodynamic evaluation is mandatory before any definitive therapy is initiated. There may be limitations on the use of certain treatments in this population (e.g., limited mobility for rapid toilet access, hand control insufficient for clean intermittent catheterization [CIC]). The role of medications used to treat PD and exacerbation of LUTS in these patients has been postulated. Some studies have shown a relationship between the degree of neurologic impairment associated with PD and LUTS. Quality of life has been shown to be directly linked to the severity of LUTS; urinary frequency and nocturia have the most deleterious impact. Overall, in a study of 110 patients, 63 (57.3%) were symptomatic from the urinary tract standpoint. No impact on LUTS was associated with use of levodopa, anticholinergics, or dopamine receptor agonists. Similar symptomatic impact occurred in both genders (Sammour et al., 2009).

Bromocriptine may have a role in the exacerbation of urgency in PD patients. In a prospective trial of 8 patients with stable PD, bromocriptine was administered followed by urodynamic and systematic assessment. Urinary urgency was found to be symptomatically exacerbated after bromocriptine administration, and this was accompanied by increased detrusor overactivity. However, there was improvement in bladder emptying associated with enhanced detrusor contractility and decreased bladder outlet resistance (Uchiyama et al., 2009). Animal models of PD have been developed using injections of 1-methyl-4-phenyl-1,2,3,6-tetrahydropyridine or 6-hydroxydopamine into the nigrostriatal pathway (Andersson, 2004; Drake et al., 2013; Wyndaele et al., 2005; Yoshimura et al., 2003).

Subthalamic nucleus deep brain stimulation has been shown to be effective for motor symptoms and dyskinesias in patients with moderate to severe PD. Clinical studies have shown that this type of stimulation improves urinary function in these patients by ameliorating bladder sensation and also improving functional bladder capacity. Herzog et al. (2006) studied 11 patients undergoing deep brain stimulation with PET scans of regional cerebral blood flow. In addition, subjects were studied with urodynamics with stimulation on and stimulation off. At urodynamic capacity, significant increases in anterior cingulate regional blood flow were noted and were increased when deep brain stimulation was off. At bladder capacity, there was also an increase in lateral frontal cortical blood flow with stimulation off. These results were thought to be indicative of deep brain stimulation improvement of bladder function by the modulation of afferent bladder information to cortical and subcortical areas (Herzog et al., 2006). Further evidence of the effect of deep brain stimulation on PD was reported by Winge and Nielsen (2012). A cohort of patients received oral medications only and was compared with a group of individuals being treated either with deep brain stimulation or with apomorphine pump for control of symptoms. A total of 170 patients were available, and outcomes reported were symptom scores (International Prostate Symptom Score [IPSS] and Danish Prostate Symptom Score [DanPSS]). There was no significant difference between the treatment groups in terms of overall symptom scores. Bladder symptom score did correlate with the stage of disease progression except for those individuals treated with deep brain stimulation, in whom symptom severity correlated to deep brain stimulation duration. Deep brain stimulation significantly decreased the amount of nocturia patients experienced (Winge and Nielsen, 2012). Witte et al. (2018) recently published a post-hoc analysis of patients undergoing deep brain stimulation of either the subthalamic nucleus or globus pallidus pars interna and found improvements in urinary frequency and incontinence; however, no significant improvement in nocturia was noted.

Sakakibara et al. (2016) published guidelines for the treatment of LUT dysfunction in PD. Botulinum toxin has demonstrated benefit in patients with PD; varying the doses of different toxin serotypes has demonstrated improvements in urinary frequency and quality of life as well as incontinence episodes for up to 9 months (Giannantoni et al., 2009; Kulaksizoglu and Parman, 2010). In addition, peripheral intermittent neuromodulation (posterior tibial nerve stimulation) has demonstrated improvements in detrusor overactivity and improved mean cystometric capacity in five of seven patients undergoing intervention (Kabay et al., 2009). Another therapy that has demonstrated some benefit for LUT dysfunction in PD is repetitive transcranial magnetic stimulation. In eight patients with advanced PD, this therapy demonstrated temporary improvement in LUTS as well as improvement in bladder capacity and first sensation on cystometric filling. The beneficial effect of this therapy was noted to last for approximately 2 weeks, consistent with findings associated with other temporary forms of neuromodulation (Brusa et al., 2009).

Multiple System Atrophy

MSA results from glial α-synucleinopathy and is a progressive neurodegenerative disease of unknown cause. The symptoms encompass parkinsonism and cerebellar, autonomic (including urinary and erectile problems), and pyramidal cortical dysfunction in a multitude of combinations. The clinical features and the differentiation from PD are nicely described in a consensus statement by Gilman et al. (1999). These investigators advocate a designation of MSA-P if parkinsonian features predominate and one of MSA-C if cerebellar features predominate. Older names such as *striatonigral degeneration*, *sporadic olivopontocerebellar atrophy*, and *Shy-Drager syndrome* (Wein, 2002a, 2002b) should be discarded in favor of these terms.

The neurologic lesions of MSA consist of cell loss and gliosis in widespread areas and occur to a significantly greater degree than with PD. This more diffuse nature of cell loss probably explains why bladder symptoms may occur earlier and be more severe than in PD, and why erectile function may be affected as well (Beck et al., 1994; Chandiramani et al., 1997; Kirby et al., 1986). Affected areas have been identified in the cerebellum, substantia nigra, globus pallidus, caudate, putamen, inferior olives, intermediolateral columns of the spinal cord, and Onuf nucleus. Males and females are equally affected, with the onset in middle age. MSA is usually progressive and associated with a poor prognosis.

Shy-Drager syndrome has been described in the past as characterized clinically by orthostatic hypotension, anhidrosis, and varying degrees of cerebellar and parkinsonian dysfunction. Voiding and erectile dysfunction are common. Some consider this to be late-stage MSA (Chandiramani et al., 1997).

Chandiramani et al. (1997) **compared the clinical features of 52 patients with probable MSA and 41 patients with PD.** For 60% of patients with MSA, urinary symptoms precede or occur with their symptoms of parkinsonism; 94% of patients with PD had been diagnosed for several years before the onset of urinary symptoms. In patients with MSA, urinary incontinence was a significant complaint in 73%; 19% had only frequency and urgency without incontinence, and 66% had a significant postvoid residual volume (100 to 450 mL). In patients with PD, frequency and urgency were the predominant symptoms in 85%, incontinence was the primary complaint in 15%, and the postvoid residual volume was elevated in only 5 of the 32 patients in whom it was measured. Eleven men with MSA underwent TURP, and 9 of these had deterioration of their urinary incontinence afterward. All 3 women with MSA were incontinent after pelvic floor repair. Five men with PD underwent prostatectomy, and 3 reported a good result. Of 27 men with MSA questioned about erectile function, 93% reported erectile failure, and in 13 of these (48%) the erectile dysfunction preceded the diagnosis of MSA. Seven of the 21 men with PD had erectile failure, but in all of these men the diagnosis of erectile dysfunction followed the diagnosis of PD by 1 to 4 years. The urogenital criteria favoring a diagnosis of MSA over PD are outlined in Box 116.1 (Fowler, 2001). Others have reported the progressive nature of LUTS associated with MSA. With time, incontinence and significant postvoid residual volume become more problematic, with steady progression of the condition in all patients (Papatsoris et al., 2008).

Box 116.1

Urogenital Criteria Favoring Diagnosis of Multiple System Atrophy

- Urinary symptoms that precede or occur with parkinsonism
- Erectile dysfunction that precedes or occurs with parkinsonism
- Urinary incontinence
- High postvoid residual volume
- Open bladder neck
- Striated sphincter denervation on electromyogram
- Worsening lower urinary tract function after urologic surgery

The initial urinary symptoms of MSA are urgency, frequency, and urgency incontinence, occurring up to 4 years before the diagnosis is made. **As would be expected from the central nervous system (CNS) areas affected, detrusor overactivity is frequently found; however, decreased compliance may also occur, reflecting distal spinal involvement of the locations of the cell bodies of autonomic neurons innervating the LUT. As the disease progresses, difficulty in initiating and maintaining voiding may occur,**

probably from pontine and sacral cord lesions, and this usually is associated with a poor prognosis. Cystourethrography or videourodynamic studies may reveal an open bladder neck, and many patients exhibit evidence of striated sphincter denervation on motor unit electromyography. The smooth and striated sphincter abnormalities predispose women to sphincteric incontinence and make prostatectomy hazardous in men.

The treatment of significant LUT dysfunction caused by MSA is difficult and seldom satisfactory. Treatment of detrusor overactivity during filling may worsen problems initiating voluntary micturition or worsen impaired contractility during emptying. **Patients usually have sphincteric insufficiency**; therefore an **outlet-reducing procedure is rarely indicated**. Conversely, drug treatment for sphincteric incontinence may further worsen emptying problems. In general, the goal in these patients is to facilitate storage, and CIC would often be desirable. Unfortunately, patients with advanced disease often are not candidates for CIC. Some patients do respond well to desmopressin administration for predominant nocturia; however, the majority of the patients do not respond well to antimuscarinic or other types of therapy (Wenning and Stefanova, 2009).

Progressive Supranuclear Palsy

Like other parkinsonian disease, progressive supranuclear palsy (PSP) is a neurodegenerative disease. It addition to parkinsonism, it is characterized by vertical gaze palsy, loss of balance, and cognitive impairment. Patients with PSP can also experience LUT symptoms, most commonly urinary frequency, urgency, and incontinence. In a study (Kim et al., 2018) including 10 patients with PSP, 90% had impaired detrusor contraction and 70% had detrusor overactivity. Sphincter abnormalities may also be present. In addition to neuronal loss of the basal ganglia, in PSP there is also loss of neurons in Onuf nucleus, reflecting the sphincter involvement that can accompany this disease (Scaravilli et al., 2000).

Diseases Primarily Involving the Spinal Cord

Multiple Sclerosis

Multiple sclerosis (MS) is primarily a disease of adults aged 20 to 50 years with a twofold predilection for women. The Multiple Sclerosis International Federation in 2016 estimated that 2.3 million people worldwide had MS. Most commonly the age of onset is 30 to 38 years of age for relapsing, remitting, and progressive phases. Common symptoms include optic nerve dysfunction, pyramidal tract abnormalities (hyperreflexia), ataxia, bowel dysfunction, neurogenic bladder, and bowel and sexual dysfunction. Primary and secondary progressive MS are predominantly spinal diseases, and their activity affects LUT function. **MS is often a progressive disease, so frequent follow-up and reassessment are indicated**.

Although the cause is not clear, the disease is believed to be immune mediated and is characterized by neural demyelination in the brain and spinal cord; it is characterized, in general, by axonal sparing (Noseworthy et al., 2000). This demyelination causes impairment of saltatory conduction and conduction velocity in axonal pathways, resulting in various neurologic abnormalities that are subject to exacerbation and remission. Lesions, known as *plaques,* range from 1 mm to 4 cm and are scattered throughout the white matter of the nervous system (Chancellor and Blaivas, 1993; Clanet, 2008). **The demyelinating process most commonly involves the lateral corticospinal (pyramidal) and reticulospinal columns of the cervical spinal cord.** It is thus not surprising that LUT dysfunction and sphincter dysfunction are so common. Autopsy studies have revealed almost constant evidence of demyelination in the cervical spinal cord, but involvement of the lumbar and sacral cord occurs in approximately 40% and 18%, respectively (Blaivas and Kaplan, 1988). Lesions may also occur in the optic nerve and in the cerebral cortex and midbrain, the latter accounting for the intellectual deterioration and/or euphoria that may accompany physical findings (Kirby, 1994; Noseworthy et al., 2000) in as many as 43% to 65% of patients (Litwiller et al., 1999).

Supraspinal neural control of micturition in MS patients was studied in a group of women using functional magnetic resonance imaging (MRI). Results demonstrated activation of the bilateral middle and right inferior frontal gyrus and the brainstem of those with neurogenic detrusor overactivity (NDO) compared with those without NDO (Khavari et al., 2017). These areas of the brain are associated with executive functioning. The authors suggest that because NDO is typically associated with urinary incontinence, activation of these areas of the brain in women with NDO is explained as an inhibition signal. In addition, women with DSD had increased activation in areas of executive functioning, emotional processing, movement, and the brainstem.

Some patients with MS demonstrate intravesical changes in receptor density and type. In a study of 18 patients with LUTS associated with MS, patients underwent evaluation with urologic assessment and urodynamics. Two groups were identified: one with pronounced NDO and minimal outflow obstruction, and the second with some degree of NDO or detrusor hypocontractility during voiding and a high degree of bladder outflow obstruction. Cold-cup biopsies were performed on all patients, and the density of calcitonin gene–related peptide (CGRP) and substance P (SP)–positive nerve fibers was noted to be higher in the first group, suggesting that denser innervation is present in patients with milder degrees of outflow obstruction and retention of detrusor contractility as compared with individuals without these findings (Radziszewski et al., 2009).

The incidence of LUT dysfunction in MS is related to disability status. Of patients with MS, **50% to 90% report voiding symptoms at some time; the prevalence of incontinence is cited as 37% to 72%** (Drake et al., 2013; Wyndaele et al., 2005). In a comprehensive review of the literature, Litwiller et al. (1999) cited symptoms of frequency or urgency in 31% to 85% of patients, incontinence in 37% to 72%, and obstructive symptoms with urinary retention in 2% to 52%. LUT involvement may constitute the sole initial complaint or may be part of the presenting symptom complex in up to 15% of patients, typically with a presentation of acute urinary retention of unknown cause or as an acute onset of urgency and frequency (Wyndaele et al., 2005).

In terms of urodynamic findings, detrusor overactivity is the most common abnormality detected, occurring in 34% to 99% of patients in reported series (Blaivas and Kaplan, 1988; Chancellor and Blaivas, 1993; Litwiller et al., 1999; Sirls et al., 1994). **Striated sphincter dyssynergia coexists with overactivity in 30% to 65% of patients. The prevalence of coexistent impaired detrusor contractility or areflexia ranges from 12% to 38%** (Drake et al., 2013; Wyndaele et al., 2005), **a phenomenon that can considerably complicate treatment efforts.** More recent estimates suggest that

62% of patients with MS have NDO with bladder outlet obstruction, 25% have NDO with DSD, 20% have detrusor underactivity, and 10% have no initial abnormal urodynamic findings. The variability and potential multiplicity of lesions associated with MS may prohibit accurate diagnosis based on urodynamics alone (Ukkonen et al., 2004).

In general, **the smooth sphincter is synergic.** Chancellor and Blaivas (1993) reviewed urodynamic findings in multiple series of patients with MS and voiding dysfunction and cited the incidence of detrusor overactivity with striated sphincter synergia to be 26% to 50% (average, 38%), detrusor overactivity with striated sphincter dyssynergia to be 24% to 46% (average, 29%), and detrusor areflexia to be 19% to 40% (average, 26%). Litwiller et al. (1999) report approximately the same ranges in a review of 22 studies. It is also possible to see relative degrees of sphincteric flaccidity caused by MS. Although this finding is relatively rare and occurs in fewer than 15% of patients (Litwiller et al., 1999), it could contribute to and predispose patients to sphincteric incontinence. De Ridder et al. (1998) reported weakness of pelvic floor contraction in almost all of the 30 women with MS whom they studied. Spasticity of the pelvic floor was present in all patients with striated sphincter dyssynergia but in none with detrusor overactivity alone. Up to 80% of patients will have neurogenic vesicourethral dysfunction at some point during the course of their disease (Fletcher and Lemack, 2009).

Sensation is frequently intact in these patients, so clinicians must be careful to distinguish urodynamic pseudodyssynergia from true striated sphincter dyssynergia. Blaivas et al. (1981) subcategorized true striated sphincter dyssynergia in patients with MS and identified some varieties that are more worrisome than others. For example, a brief period of striated sphincter dyssynergia during detrusor contraction in a woman with MS may be relatively inconsequential, as long as it does not result in excessive intravesical pressure during voiding, substantial postvoid residual urine volume, or secondary detrusor hypertrophy. However, more sustained episodes of striated sphincter dyssynergia that result in high bladder pressures of long duration are most associated with urologic complications. Giannantoni et al. (1998) likewise concluded that there was a significant relationship between the maximum amplitude of the involuntary bladder contractions and upper urinary tract deterioration in their MS population of 116 patients. Chancellor and Blaivas (1993) emphasized what they believed were **the most important parameters predisposing patients with MS to significant urologic complications: (1)**

striated sphincter dyssynergia in men; (2) high detrusor filling pressure; and (3) an indwelling catheter. Wyndaele's committee (Drake et al., 2013; Wyndaele et al., 2005) **concluded that progressive neurologic disease in patients with MS rarely causes upper urinary tract damage, even when severe spasticity and disability exist.** The reason for this is unknown, but the committee proposed that the situation and concerns with respect to MS were unlike those for SCI. In contrast, a series of 141 patients with MS found that disability status was a risk factor for urodynamic abnormalities (poor compliance and vesicoureteral reflux [VUR]) that can cause upper tract damage (Ineichen et al., 2018). Patients with MS and LUTS should undergo evaluation with history, physical examination, and urodynamic testing given the high likelihood LUT dysfunction and the potential for upper tract damage.

Aggressive and anticipatory medical management can obviate most of the significant complications. Sirls et al. (1994) reported that less than 10% of their patients required surgical intervention resulting from failure of aggressive medical management and that none developed hydronephrosis on such therapy. The regimens used were (1) medications to decrease detrusor overactivity plus CIC (57%); (2) medications alone (13%); (3) CIC alone (15%); and (4) behavioral therapy. **Caution should be exercised in recommending irreversible therapeutic options, because a significant proportion of patients with MS with and without new symptoms will develop changes in their detrusor compliance and urodynamic pattern** (Ciancio et al., 2001). No factors appear to be predictive of upper tract changes in MS. In a 4-year follow-up of 113 MS patients, 66 underwent both urodynamic and renal ultrasound testing. Eleven of the 66 patients (17%) had abnormal ultrasound findings; the most significant finding was minor caliectasis of no clinical significance. Neither creatinine nor urodynamic findings were associated with the abnormal renal ultrasound findings (Lemack et al., 2005). **Others have noted the lack of predictability of urinary symptoms for disease status, making baseline testing with urodynamics critical to disease assessment and management** (Nakipoglu et al., 2009). Surgical intervention for MS appears to be diminishing with improved pharmacologic management and the realization of the alternating neurologic picture of lower urinary dysfunction associated with MS (Togami et al., 2013; Ukkonen et al., 2004).

Physiotherapeutic management has demonstrated success for this condition. In an Australian trial with 73 patients with MS, 40 patients were randomized to an individualized bladder rehabilitation program that included baseline assessment

(3-day voiding charts, fluid balance, intake restrictions, postvoid residual measurement, and urodynamics). Subsequently, bladder re-education, pelvic floor exercises, and instruction in techniques for improved bladder emptying and a bowel program were instituted. A nonintervention group served as control. Substantial improvements in all subjective quality-of-life indicators were noted in the intervention group, as compared with the nonintervention group, demonstrating the benefit of a bladder and bowel regimen in this population (Khan et al., 2009).

At present, there is no consensus on optimal bladder management for patients with MS, and management is most commonly predicated on symptomatic and urodynamic findings. On the basis of expert consensus, De Ridder et al. (2005) concluded that in early MS, anticholinergics and CIC were considered to be the cornerstones of therapy. For patients with advanced MS (with an Expanded Disability Status Scale [EDSS] score >7), specific guidelines are still lacking. In general, Credé voiding or Valsalva voiding is contraindicated, especially in the presence of DSD. The committee further recommended that indwelling catheters be reserved for patients for whom all other possible treatments have failed. In the approximately 30% of patients with MS using indwelling urinary catheters, the suprapubic route is the preferred route in men and women. This form of management is considered reasonable for that subpopulation, as long as vigilant long-term follow-up is maintained (De Ridder et al., 2005).

The role of onabotulinum toxin therapy for bladder overactivity related to MS has been reported. Detrusor overactivity suppressed with onabotulinum toxin injection can provide social continence and improved quality of life. Stability of response and safety have been reported over treatment periods as long as five cycles. Kennelly et al. (2013) reported long-term experience with 387 patients with NDO caused by either MS or SCI and found that 73% to 94% of patients reported incontinence episode reductions of at least 50% depending on treatment cycle assessed.

Sacral neuromodulation may have an emerging role in MS and has shown to be effective and safe in small series (Engeler et al., 2015). However, the limiting feature at this time is that current sacral neuromodulation systems are not compatible with MRI systems, a not infrequent imaging modality used during the management of MS. As understanding of the disease process of MS and its effects on micturition expands, the hope is for new treatment strategies in the future.

Spinal Cord Injury

Epidemiology, Morbidity, General Concepts

SCI may occur as a consequence of acts of violence, fracture, or dislocation of the spinal column secondary to motor vehicle collisions, diving accidents or falls, vascular injuries or surgical repairs, infection, disk prolapse, or sudden and/or severe hyperextension from other causes. Altered LUT and sexual function frequently occur secondary to SCI and have a significant impact on quality of life. SCI patients are at risk urologically for urinary tract infection (UTI), sepsis, upper urinary tract and LUT deterioration, upper urinary tract and LUT calculi, autonomic hyperreflexia (dysreflexia), skin complications, and depression (which can complicate urologic management). Failure to properly address the LUT dysfunction can lead to significant morbidity and mortality. There is great variation in urologic practice regarding initial evaluation, follow-up, and surveillance among spinal injury units (Bycroft et al., 2004), a problem that Boone (2004) properly attributes to a lack of evidence-based decision making.

Complete anatomic transection of the spinal cord is rare, and the degree of neurologic deficit varies with the level and severity of the injury. **Spinal column (bone) segments are numbered by the vertebral level, and these have a different relationship to the spinal cord segmental level at different locations. Discussions of SCI must include cord or column level. The sacral spinal cord begins at about spinal column level T12 to L1. The spinal cord terminates in the cauda equina at approximately the spinal column level of L2.** Multiple-level injuries may occur, and, even with a single isolated initial injury, cord damage may not remain confined to a single cord segment and may extend cephalad, caudad, or both.

The National SCI Database (2016) estimates that the annual rate of SCI is 54 cases per million persons in the United States or about 17,000 new SCI cases per year. The prevalence in the United States was approximately 282,000 persons living with SCI. The most common mechanisms of injury are motor vehicle accidents (38%), falls (30.5%), violence (13.5%), and sports-related injuries (9%). Males account for 80% of patients with SCI. From 1973 to 1979, the average age at injury was 28.7 years. However, as the median age of the general population of the United States has increased by approximately 9 years since the mid-1970s, the average age at injury has also steadily increased over time. In 2016 the average age at injury was 42 years. Children constitute 3% to 5% of all patients with SCI (Generao et al., 2004). The National SCI Database reported that neurologically incomplete quadriplegics constituted the largest group of SCI patients at the time of hospital admission (45%), followed by incomplete paraplegics (21.3%), complete paraplegics (20%), and complete quadriplegics (13.3%%). Less than 1% of persons experienced complete neurologic recovery by hospital discharge. The majority of SCIs occur at or above the T12 spinal column (vertebral) level, with injury to one of the eight cervical segments accounting for the patients with tetraplegia and with patients with paraplegia having injury in the thoracic, lumbar, or sacral regions of the spinal cord.

SCI is associated with long-term urologic functional compromise. In an assessment of 236 patients with mean follow-up of 24 years, 43% of patients continue to report incontinence at time of follow-up, with paraplegics reporting daily incontinence more frequently than tetraplegics (presumably because of catheter dependence of the latter group). Only 19% of patients used some form of medication for assistance in management of their incontinence. Surprisingly, CIC was associated with higher rates of incontinence than other types of bladder drainage techniques (Hansen et al., 2010).

Although earlier data (Hackler, 1977) **indicated that renal disease was the major cause of death, at least in the paraplegic patient, a retrospective study of more than 5000 patients who sustained SCI between 1973 and 1980 revealed that the leading causes of death at that time were pneumonia, septicemia, pulmonary emboli, heart disease, accidents, and suicide** (Soden et al., 2000; Stover and Fine, 1987). These figures seemingly indicate a distinct improvement in the urologic care of these patients. Impaired mobility is commonly noted in the SCI patient and may substantially affect urinary habits and continence (Biering-Sorensen et al., 2004). Urologic phenomena also figure prominently in chronic SCI; approximately 7% of patients will develop an initial kidney stone within 10 years after initial injury. The greatest risk occurs during the first 3 months after injury, and 98% of these stones will be apatite or struvite in composition. There appear to be two specific time frames for stone formation in this population, one being the acute phase associated with hypercalciuria from immobilization. A more chronic phase stone formation period that usually is associated with chronic catheter management occurs years after injury and predominately involves the LUT (Post and Noreau, 2005).

Controlled and coordinated LUT function depends on an intact neural axis. Bladder contractility and the occurrence of reflex contractions depend on an intact sacral spinal cord and its afferent and efferent connections.

Key Points: Spinal Cord Injury

- In general, complete SCI above the sacral spinal cord but below the area of the sympathetic outflow results in detrusor overactivity, absent sensation below the level of the lesion, smooth sphincter synergia, and striated sphincter dyssynergia.
- Lesions at or above the spinal cord level of T7 or T8 (the spinal column level of T6) may result in smooth sphincter dyssynergia as well.
- Neurologic examination is no substitute for urodynamic evaluation in these patients in determining risk factors and treatment.

Bladder dysfunction associated with acute SCI has been investigated in a variety of animal models. In rodent models using a moderate contusion injury at three different thoracic levels—T1, T4, or T9—versus complete crush injury at T1 and T9, differences in bladder function were noted. T4 and T9 contusions were associated with a relative increase in urinary retention, whereas T1 defects had less impact on retained volume. Lesions at T1 spared a critical descending modulating pathway for voiding in rats. Crush injuries were associated with much more defect emphasis (David and Steward, 2010). Receptor behavior has also been noted to change in SCI. Differential expression of channel receptors has been demonstrated in muscle strips from neurogenic patients. K_{ATP} calcium channels appear to regulate spontaneous hyperactivity in neurogenic patients as compared with normal individuals. However, BK_{Ca} channels are more involved in regulation of normal patients as compared with neurogenic patients (Oger and AlKhawajah, 2010).

These topics are not further specifically considered in detail here, nor are the ramifications of this information relative to potential improvement of SCI after stem cell implant or reinnervation. Reviews can be found by Olson (1997); Fawcett (1998); Kakulas (1999); Rabchevsky and Smith (2001) (this also includes a discussion of pathophysiology and experimental models); Cao et al. (2002) (stem cell repair); Fawcett (2002) (repair of SCI); Rossi and Cattaneo (2002) (stem cell therapy); Mitsui et al. (2003) (stem cell repair); Kakulas (2004) (neuropathology and natural history of the spinal cord changes); and Livshits et al. (2004) (reinnervation). A recent review of SCI and regeneration by Chhabra and Sarda (2017) discussed advances in cellular therapeutics promoting axonal regrowth.

Sexual and reproductive dysfunction in the patient with SCI is a topic that deserves much attention in the overall rehabilitation plan but is beyond the scope of this chapter. Pertinent general and specific concepts of sexual and reproductive dysfunction and their normalization in this special group of patients can be found in Chapters 26, 30, and 32. Other excellent reviews on the specifics of sexual function in SCI are those by Bennett et al. (1988), Smith and Bodner (1993), and Biering-Sorensen and Sonksen (2001), and on infertility by Linsenmeyer and Perkash (1991), Rajaskaran and Monga (1999), and Rutkowski et al. (1999).

Spinal Shock

A period of “spinal shock” may be expected after an SCI, defined as decreased excitability of spinal cord segments at and below the level of the lesion. There is **absent somatic reflex activity and flaccid muscle paralysis below this level.** Although classic teaching refers to generalized areflexia below the level of the lesion for days to months, Thomas and O'Flynn (1994) confirm that the most peripheral somatic reflexes of the sacral cord segments (the anal and bulbocavernosus reflexes) may never disappear or, if they do, may return within minutes or hours of the injury. However, functions proximal to the level of the injury may be depressed as well (Atkinson and Atkinson, 1996), which is felt to be a result of rearrangement of spinal cord pathways. Although the course of spinal shock is well known, the actual pathophysiology remains poorly understood. From animal models, with the first hours of initial injury signs of trauma appear in the gray matter followed by protein accumulation. Reperfusion injury may also play a role in cellular injury, but it is not clearly understood.

Spinal shock includes a suppression of autonomic activity as well as somatic activity, and the bladder is acontractile and areflexic. Radiologically, the bladder has a smooth contour with no evidence of trabeculation. The bladder neck is usually closed and competent, unless there has been prior surgery or the patient has sustained a potential thoracolumbar and presumably sympathetic injury (Sullivan and Yalla, 1992). **The smooth sphincter mechanism appears to be functional. Some electromyographic activity may be recorded from the striated sphincter, and the maximum urethral closure pressure is lower than normal but still maintained at the level of the external sphincter zone. However, the normal guarding reflex (striated sphincter response during filling) is absent, and**

there is no voluntary control (Fam and Yalla, 1988). Because sphincter tone exists, urinary incontinence usually does not result unless there is gross overdistention with overflow. In evolving lesions, every attempt should be made to preserve as low a bladder storage pressure as possible. **Urinary retention is the rule,** and catheterization is necessary to circumvent this problem. Although almost all would agree that CIC is an excellent and preferred method of management during this period, Lloyd et al. (1986) reported their own experience and that of others that indicate no differences in outcome when a small-bore indwelling urethral catheter or suprapubic tube is used at this stage.

If the distal spinal cord is intact but is simply isolated from higher centers, there is usually a return of reflex detrusor contractility. At first, such reflex activity is poorly sustained and produces only low-pressure changes, but the strength and duration of such involuntary contractions typically increase, producing involuntary voiding, usually with incomplete bladder emptying. This return of reflex bladder activity typically manifests with involuntary voiding between catheterizations and occurs along with the recovery of lower extremity deep tendon reflexes (DTRs). Spinal shock usually lasts 6 to 12 weeks in complete suprasacral spinal cord lesions but may last up to 1 or 2 years. It may last a shorter period of time in incomplete suprasacral lesions.

Suprasacral Spinal Cord Injury

There is no consensus agreement on the neurobiology of the development of reflex bladder contraction in response to bladder distention after suprasacral SCI. de Groat et al. (1997) have studied this phenomenon extensively in cats and listed four potential mechanisms for the recovery of such micturition and the development of C-fiber afferent evoked bladder reflexes: (1) elimination of bulbospinal inhibitory pathways; (2) strengthening of existing synapses, or formation of new synaptic connections from axonal sprouting in the spinal cord; (3) changes in synthesis, release, or actions of neurotransmitters; and (4) alterations in afferent input (afferent axonal sprouting) from peripheral organs. Reports of specific alterations in animal models are summarized by Morrison et al. (2005) as (1) increased sensitivity of C-fiber afferents, possibly involving NGF; (2) enlargement of dorsal root ganglion cells; (3) increased electrical excitability of afferents associated with a shift in expression of sodium channels from a high-threshold tetrodotoxin-resistant type to a low-threshold tetrodotoxin-sensitive type. Other findings possibly related to the development of LUT dysfunction after SCI have been reported as (1) increased concentrations of glutamate, glycine, and taurine (Smith et al., 2002); (2) disruption of bladder epithelium barrier function (Apodaca et al., 2003); (3) change from low affinity M_1 to high affinity M_3 receptors at pre-junctional cholinergic nerve endings (Somogyi et al., 2003); (4) increased release of adenosine triphosphate (ATP) from bladder urothelium (Khera et al., 2004); (5) increased spinal cord NGF (Seki et al., 2004); and (6) alterations in smooth muscle myosin heavy chain gene expression (Wilson et al., 2005). In murine models of acute SCI, nicotinic or purinergic receptor mechanisms have been shown to be the primary mechanism for ATP release because atropine has been shown to be only partially effective in stimulating ATP release (predominantly a muscarinic receptor phenomenon in the absence of injury). These findings further indicate a change in receptor-mediated bladder activity associated with SCI (Salas et al., 2007). Yet another mechanism of bladder dysfunction may arise from modulation of TRPA-1 receptors, which has been shown to attenuate bladder overactivity in SCI models, indicating the importance of these receptors in the spinal cord–injured bladder (Andrade et al., 2011).

The characteristic pattern in a patient with a complete lesion above the sacral spinal cord is detrusor overactivity, smooth sphincter synergia (with lesions below the sympathetic outflow), and striated sphincter dyssynergia (Chancellor and Blaivas, 1995a; Sullivan and Yalla, 1992; Thomas and O'Flynn, 1994). **Neurologic examination shows spasticity of skeletal muscle distal to the lesion, hyperreflexic DTRs, and abnormal plantar responses. There is impairment of superficial and deep sensation.** Figs. 116.1 to 116.3 typify the cystourethrographic and urodynamic patterns. The guarding reflex is absent or weak in most patients with a complete suprasacral SCI. In incomplete lesions the reflex is often preserved but variable (Morrison et al., 2005). The striated sphincter dyssynergia causes a functional obstruction with poor emptying and high detrusor pressure. In an effort to subclassify detrusor sphincter dyssynergia, Karsenty et al. (2005) retrospectively evaluated videourodynamic recordings of patients with complete SCI with untreated neurogenic overactive bladder and detrusor sphincter dyssynergia. They identified two time periods within the tracings, with Delay A being defined as that period between the onset of external urethral sphincter (EUS) pressure increase and the subsequent onset of bladder pressure increase. Delay B was defined as the period between the onset of urethral sphincter pressure increase and the moment at which bladder pressure increase reached a level of 10 cm H_2O or greater above the baseline value. The recordings of 20 patients were assessed, with the Delay A timeframe found to be significant in 16 of 20 patients, with a mean time for delay of 2.2 seconds. There was a positive association between this delay and the completeness of the SCI and the presence of continuous DSD on electromyogram. Delay B was positive in all patients with a mean delay time of 7.6 seconds. The authors concluded that EUS contraction starts before the onset of bladder contraction in most patients with coexistent SCI and detrusor sphincter dyssynergia.

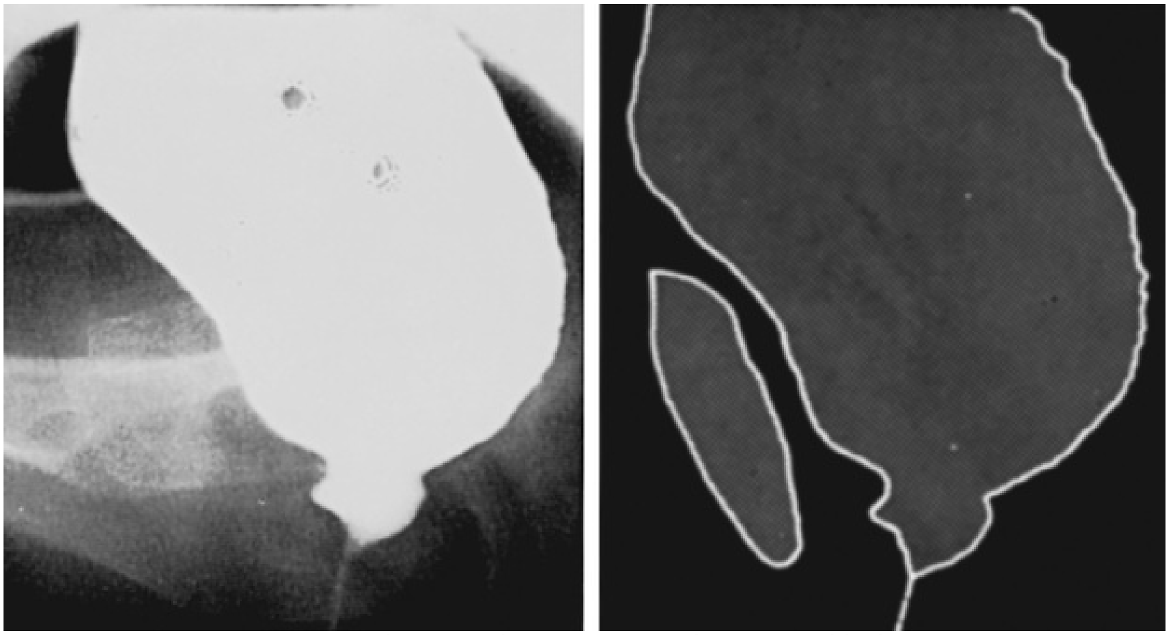

FIG. 116.1 Cystourethrogram in a 19-year-old woman with detrusor-striated sphincter dyssynergia secondary to a complete spinal cord injury at vertebral level T11. Image was taken during an involuntary bladder contraction with exaggerated bladder neck opening caused by the obstruction below. (From Nordling J, Olesen KP: Basic urographic and cystourethrographic patterns. In Pollack HM, editor: *Clinical urography*, Philadelphia, 1990, Saunders, p 1953.)

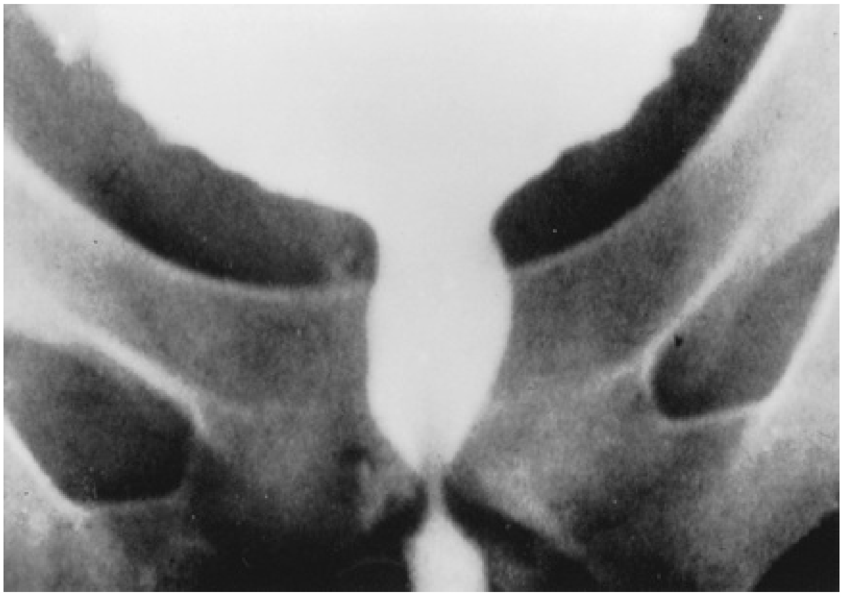

FIG. 116.2 Typical cystourethrographic configuration of a synergic smooth sphincter and a dyssynergic striated sphincter in a man during a bladder contraction. (From Nanninga JB: Radiological appearances following surgery for neuromuscular diseases affecting the urinary tract. In Pollack HM, editor: *Clinical urography,* Philadelphia, 1990, Saunders, p 2003.)

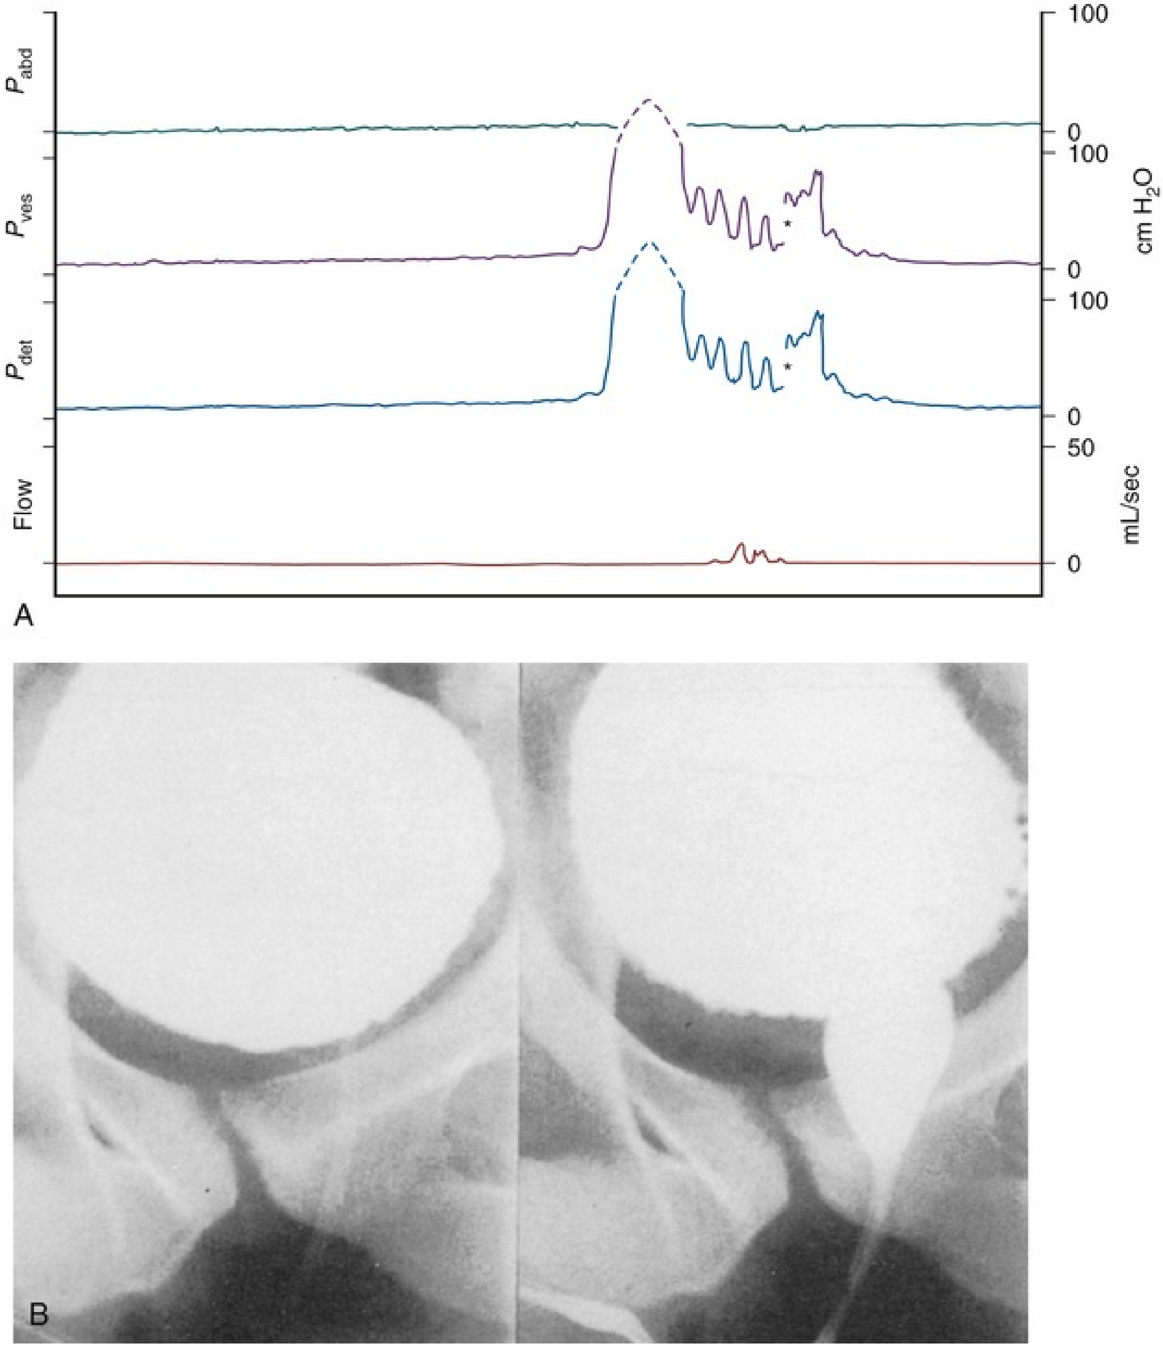

FIG. 116.3 Video images in B at corresponding points of the urodynamic tracings in A. Detrusor hyperreflexia (Pdet 150 cm H_2O), synergic bladder neck, dyssynergic striated sphincter. The *asterisk* represents a range change from a scale of 0 to 100 cm H_2O. (From Lawrence WT, Thomas DC: Urodynamic techniques in the neurologic patient. In O'Reilly PH, George NJR, Weiss RM, editors: *Diagnostic techniques in urology,* Philadelphia, 1990, Saunders, p 360.)

The presence of striated sphincter dyssynergia causes a functional

obstruction with poor emptying and high detrusor pressures. Occasionally, incomplete bladder emptying may result from what seems to be a poorly sustained or absent detrusor contraction. This seems to occur more commonly in lesions close to the conus medullaris than with more cephalad lesions. This may result from a second occult lesion or may be caused by locally functioning reflex arcs, which result in detrusor inhibition from strong striated pelvic floor muscle contraction, or by a loss of higher center–mediated detrusor facilitation, which normally occurs after the initial increase in pressure during a bladder contraction (Thomas and O'Flynn, 1994). Once reflex voiding is established, it can be initiated or reinforced by the stimulation of certain dermatomes, such as by tapping the suprapubic area. The urodynamic and upper tract consequences of the striated sphincter dyssynergia vary with severity (usually worse in complete lesions), duration (continuous contraction during detrusor activity is worse than intermittent contraction), and anatomy (male is worse than female) (Linsenmeyer et al., 1998).

The type of dyssynergia also appears to be associated with degree of injury and potential for progression of dysfunction. Schurch et al. (2005) evaluated 105 male patients with SCI and noted a correlation between the type of DSD and completeness of spinal cord lesion. Men with incomplete sensory and motor lesions more commonly had type 1 DSD (increase in detrusor pressure and electromyographic activity), whereas complete sensory and motor lesions were more commonly associated with either type 2 (sporadic contractions of the striated sphincter throughout detrusor contraction) or type 3 DSD (crescendo-decrescendo pattern of sphincter contraction). However, there was no correlation noted between the type of DSD and the lesion level. At long-term follow-up, DSD type was noted to evolve from type 2 or type 3 DSD in approximately a quarter of the studied patients, whereas 65% of patients remained stable with the same type of DSD at follow-up (Schurch et al., 2005).

From a functional standpoint, the voiding dysfunction most commonly seen in suprasacral SCI represents a filling or storage and an emptying or voiding failure. If bladder pressures are suitably low or if they can be sufficiently and safely lowered with nonsurgical or surgical management, the problem can be treated primarily as an emptying failure. CIC can then be continued as a safe and effective way of satisfying many of the goals of treatment. The role of additive antimuscarinic administration appears to be supported by the preponderance of evidence in this patient population (Madersbacher et al., 2012). Consensus opinion has stressed the conservative use of antibiotics in patients using long-term CIC. Wyndaele (2012) expressed the importance of demonstrating definitive evidence of UTI before initiating antimicrobial therapy. Alternatively, sphincterotomy or intrasphincteric injection of onabotulinumtoxinA can be used in males to lower the detrusor leak point to an acceptable level and render the patient incontinent, thus converting the dysfunction primarily to a storage failure (incontinence), which can be obviated either by timed stimulation or with an external collecting device. In the dexterous SCI patient, the former approach using CIC is becoming predominant. Electrical stimulation of the anterior sacral roots with some form of deafferentation is also now a distinct reality (Creasey et al., 2001; Seif et al., 2004). Ongoing investigations with ventral nerve surgery (Lam Van Ba et al., 2018) and use of stem cells may completely change the paradigm of suprasacral cord injury management in the future (Snyder and Teng, 2012).

Key Points: Management of Patients With Suprasacral Spinal Cord Injury

- The characteristic urodynamic pattern is detrusor overactivity, smooth sphincter synergia (with lesions below the sympathetic outflow), and striated sphincter dyssynergia.
- A careful initial evaluation and periodic, routine follow-up evaluation must be performed to identify and correct risk factors and potential complications: high-pressure storage, high detrusor leak point pressure, VUR, stone formation (lower and upper tracts), and complicating infection, especially in association with reflux.
- Avoid use of long-term antibiotics to prevent infection in patients performing CIC.
- Ongoing investigations with ventral nerve surgery and use of stem cells may completely change the paradigm of suprasacral cord injury management.

Sacral Spinal Cord Injury

After the patient has recovered from spinal shock, there is **typically a depression of DTRs below the level of a complete lesion with varying degrees of flaccid paralysis. Sensation is usually absent below the lesion level. Detrusor areflexia with high or normal compliance is the common**

initial result. However, decreased compliance may also develop, a finding in some distal SCI lesions that most likely represents a complex response to neurologic decentralization probably involving reorganization and plasticity of neural pathways (Blaivas et al., 1998b; de Groat et al., 1997; Fam and Yalla, 1988). There is surprisingly little consensus on the evolution of the appearance or function of the bladder neck or smooth sphincter area after sacral SCI. **The classic outlet findings are described as a competent but nonrelaxing smooth sphincter and a striated sphincter that retains some fixed tone but is not under voluntary control. Closure pressures are decreased in both areas** (Sullivan and Yalla, 1992; Thomas and O'Flynn, 1994). The late appearance of the bladder neck may be “open” (Kaplan et al., 1991). Attempted voiding by straining or Credé maneuver results in “obstruction” at the level of the potentially closed bladder neck or at the distal sphincter area if the sphincter tone is fixed (Fam and Yalla, 1988; Thomas and O'Flynn, 1994). Fig. 116.4 illustrates the typical cystourographic and urodynamic pictures of the late phases of such a complete lesion.

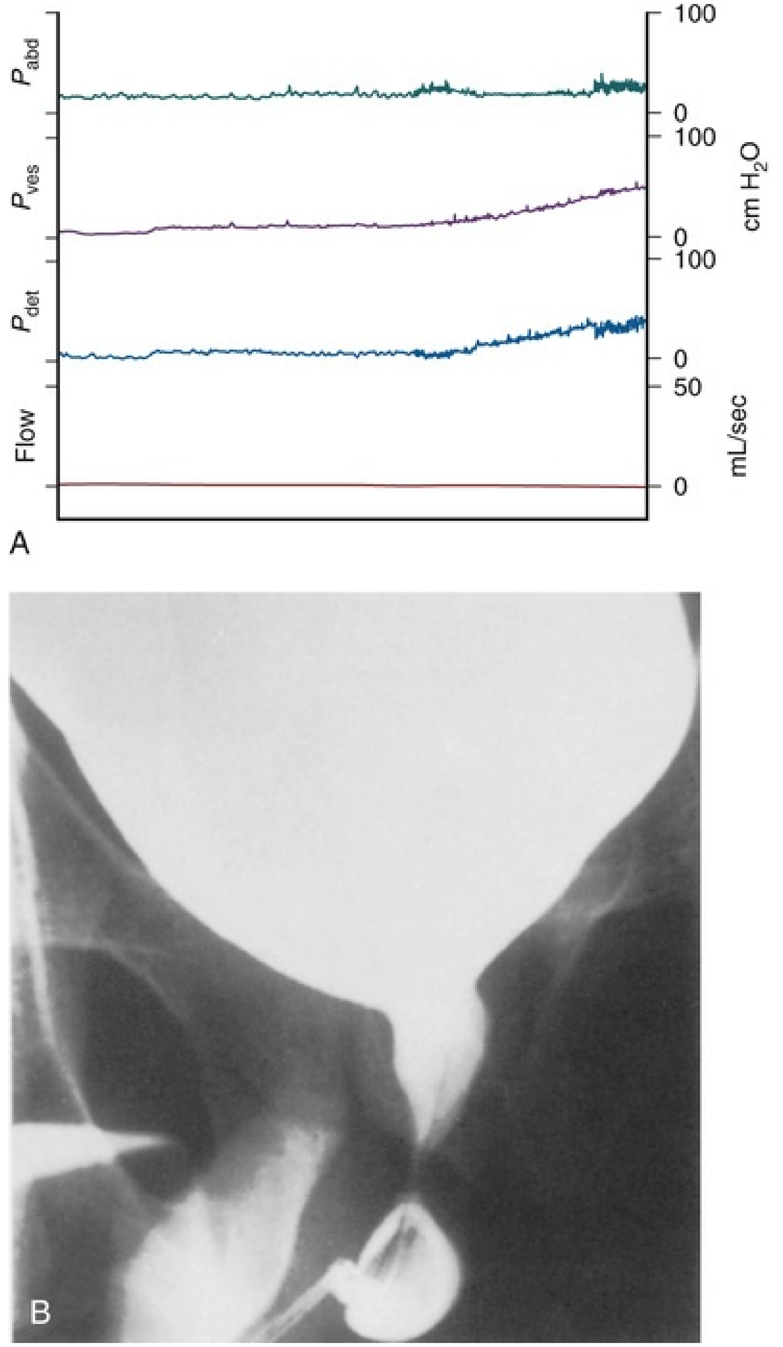

FIG. 116.4 Simultaneous video (B) and urodynamic study (A) from a 28-year-old man whose bladder has been filled with 420 mL of contrast material. There is low compliance; the bladder neck is incompetent; and with straining, the distal sphincter mechanism does not open—a pattern often seen in sacral spinal cord or efferent nerve root injury or disease. (From Lawrence WT, Thomas DC: Urodynamic techniques in the neurologic patient. In O'Reilly PH, George NJR, Weiss RM, editors: *Diagnostic techniques in urology,* Philadelphia, 1990, Saunders, p 362.)

Key Points: Management of Patients With Sacral Spinal Cord Injury

- Potential risk factors and complications are those previously described, with particular emphasis on storage pressure, which can result in silent upper tract decompensation and deterioration in the absence of VUR.
- Treatment is usually directed toward producing or maintaining low-pressure storage while circumventing emptying failure with CIC when possible. Pharmacologic and electrical stimulation may be useful in promoting emptying in certain circumstances.

Neurologic and Urodynamic Correlation

Although generally correct, the correlation between somatic neurologic findings and urodynamic findings in suprasacral and sacral SCI patients is not exact. A number of factors should be considered in this regard. First, whether a lesion is complete or incomplete is sometimes a matter of definition, and a complete lesion, somatically speaking, may not translate into a complete lesion autonomically and vice versa. In addition, multiple injuries may actually exist at different levels, even though what is seen somatically may reflect a single level of injury. Further demonstration of the unpredictability of LUT status in patients with incomplete lesions was reported by Patki et al. (2006), who assessed a group of 43 men and 21 women with incomplete SCI (American Spinal Injury Association [ASIA] grades D and E) during a 2-year period. Forty patients initially assessed as having a bladder not at risk for deterioration ultimately experienced deterioration requiring CIC. Conversely, 5 of 20 patients who initially required CIC no longer required this with time. In long-term follow-up, 68% of patients continued to have abnormal urodynamic findings, and 37% of patients required a change in urologic management in the absence of perceptible change in neurologic status, indicating the potential for continued bladder changes in the absence of other detectable neurologic disease (Patki et al., 2005).

In a classic article, Blaivas (1982) correlated clinical and urodynamic data from 550 patients with LUT dysfunction. In 155 patients with complete and incomplete suprasacral neurologic lesions, physiologically normal voiding was reported in 41%. DSD was demonstrated in 34%, and, surprisingly (and seemingly paradoxically), detrusor areflexia was noted in 25%. Other authors have noted detrusor areflexia with suprasacral SCI or disease with hypothesized causes of a coexistent distal spinal cord lesion or a disordered integration of afferent activity at the sacral root or cord level (Beric and Light, 1992; Light et al., 1985). DSD was reported in 45% of 119 patients with suprasacral spinal cord lesions, whereas none of 36 patients with supraspinal neurologic lesions had DSD. These data support prior conclusions that **(1) coordinated voiding is regulated by neurologic centers above the spinal cord and (2) a diagnosis of striated sphincter dyssynergia implies a neurologic lesion that interrupts the neural axis between the pontine-mesencephalic reticular formation and the sacral spinal cord.** All 27 patients with neurologic lesions above the pons who were able to void did so synergistically (i.e., with relaxation of the striated sphincter followed by detrusor contraction). Twenty of these patients had detrusor overactivity, but 12 of the 20 had voluntary control of the striated sphincter, supporting a thesis of separate neural pathways governing voluntary control of the bladder and of the periurethral striated musculature. Most of these patients with detrusor overactivity secondary to suprapontine lesions were able to voluntarily contract the striated sphincter, but without abolishing bladder contraction. This seems to indicate that the inhibition of bladder contraction by pudendal motor activity is not merely a simple sacral reflex, but rather a complex neurologic event. Twenty-two of these patients had evidence of either sacral or infrasacral neurologic impairment of bladder function with suprasacral control of striated sphincter function or vice versa. This provides a clinical correlate to the separate anatomic locations of the parasympathetic motor nucleus and the pudendal nucleus in the sacral spinal cord.

Wyndaele (1997) correlated the neurologic and urodynamic data in 92 patients with SCI and came to the same general conclusion: **Although there was a general correlation between the neurologic level of injury and the expected vesicourethral function, it was neither absolute nor specific, especially in the group of patients with paraplegia resulting from spinal cord lesions at column level T10 to L2.** With reference to this latter group, Pesce et al. (1997) reported on 46 patients with complete SCIs from vertebral lesions between T11 and L2: 50% of the patients had detrusor areflexia and 50% had detrusor overactivity. Of the patients with detrusor overactivity, 16 also had DSD. Of 22 patients with lesions above vertebral level L1, 8 showed areflexia and 14 showed detrusor overactivity, of whom 9 demonstrated DSD. Of 9 patients with a lesion between T12 and L1, 3 showed detrusor areflexia and 6 overactivity, of whom 4 showed DSD. Of 15 patients with a lesion at L1 or lower, 3% showed detrusor overactivity and DSD.

Based on their review of 243 post-traumatic SCI patients who underwent complete spinal computed tomography (CT) or MRI, Weld and Dmochowski (2000) agreed that the correlation between somatic neurologic findings or spinal imaging studies and urodynamic findings in SCI patients is not exact. The authors’ correlation between level of injury and urodynamic findings was better than those previously reported, most likely attributable to the precision of the radiologic imaging studies. Of 196 patients with suprasacral injuries, 94.9% demonstrated overactivity and/or DSD, 41.8% had low bladder compliance (defined as 12.5 mL/cm H_2O), and 40.3% had detrusor leak point pressures greater than 40 cm H_2O. Of the 14 patients with sacral injuries, 85.7% demonstrated detrusor areflexia; 78.6%, low compliance; and 85.7%, high leak point pressures. Of 33 patients with combined suprasacral and sacral injuries, 68% demonstrated detrusor overactivity and/or DSD, 27% had areflexia, 58% had low compliance, and 61% had high leak point pressures.

Other factors such as underlying histology may also contribute to upper tract deterioration. Ozkan et al. (2006) performed full-thickness bladder biopsies in a group of patients undergoing augmentation cystoplasty for NDO. A relationship between the degree and severity of detrusor fibrosis was noted to be a significant risk factor for upper tract deterioration. In addition, leak-point pressures of greater than 75 cm H_2O were also found to be consistent with upper tract deterioration (Ozkan et al., 2006). Recent data suggest that detrusor overactivity occurring greater than one-third the duration of bladder filling is associated with renal damage in SCI (Elmelund et al., 2017). **Aggressive treatment of NDO should be undertaken in SCI patients to prevent long-term upper tract damage.**

The International Continence Society published a paper on good urodynamic practices to improve urodynamic methods (Rosier et al., 2017). Data reviewed on urodynamic evaluation for neurogenic lower urinary tract dysfunction suggested wide variation in same-setting repeat urodynamic parameters such as cytometric capacity, storage pressures, and voiding data but good correlation in the detection of detrusor overactivity. This suggests that **a single urodynamic study may not provide an adequate picture of the patient's LUT function, and repeated evaluations may be necessary to make accurate clinical assessments.**

In summary, all of these data suggest that **management of the urinary tract**

in such patients must be based on urodynamic principles and findings rather than inferences from the neurologic history and evaluation. Conversely, clinicians should not draw neurologic conclusions solely on the basis of urodynamic findings, although the information regarding complete lesions is, for the most part, valid (Cameron et al., 2012; Lenherr and Clemens, 2013). **Regular urodynamic follow-up is recommended to evaluate changes over time, assess response to treatments, and prevent upper tract damage** (Schurch et al., 2018).

Autonomic Dysreflexia

First described by Guttmann and Whitteridge in 1947, autonomic hyperreflexia (autonomic dysreflexia) is a potentially fatal emergency unique to the SCI patient. Excellent source materials include the reviews by Trop and Bennett (1991), Vaidyanathan et al. (1998), and Karlsson (1999). **Autonomic hyperreflexia represents an acute massive disordered autonomic (primarily sympathetic) response to specific stimuli in patients with SCI above the cord level of T6 to T8 (the sympathetic outflow).** It is more common in cervical (60%) than thoracic (20%) SCI. Onset after injury is variable—usually soon after spinal shock, but it may occur up to years after injury, and distal spinal cord viability is a prerequisite.

Symptomatically, autonomic hyperreflexia is a **syndrome of exaggerated sympathetic activity in response to stimuli below the level of the lesion. The symptoms include pounding headache, hypertension, and flushing and sweating of the face and body above the level of the lesion. Bradycardia is a typical accompaniment, although tachycardia or arrhythmia may occur. Hypertension may vary in severity** from causing a mild headache before voiding to life-threatening cerebral hemorrhage or seizure.

The stimuli for this exaggerated response commonly arise from the bladder or rectum and typically involve distention. Precipitation may be the result of simple LUT instrumentation, tube change, catheter obstruction, or clot retention, and in such cases the symptoms resolve quickly if the stimulus is withdrawn. Additional causes or exacerbating factors may include other upper urinary tract or LUT pathology (e.g., calculi), gastrointestinal pathology, long bone fracture, sexual activity, electrocoagulation, and decubitus ulcers. Risk factors for autonomic dysreflexia during urodynamic evaluation include complete injury, cervical-level of injury, presence of detrusor sphincter dyssynergia, poor bladder compliance, and more than 2 years since injury (Liu et al., 2017). **In addition, with more SCI patients participating in athletic pursuits, the instigation of this condition related to sports activities is also being increasingly recognized** (Krassioukov, 2012).

DSD invariably occurs, and, at least in males, smooth sphincter dyssynergia is also usually a part of the syndrome. The pathophysiology is that of nociceptive stimulation via afferent impulses that ascend through the cord and elicit reflex motor outflow, causing arteriolar, pilomotor, and pelvic visceral spasm and sweating. Normally, the reflexes would be inhibited by secondary output from the medulla, but because of the SCI this does not occur below the lesion level. Vaidyanathan et al. (1998) emphasized that the SCI disrupts control of the sympathetic preganglionic neurons because bulbospinal input has been lost, and the remaining regulation is accomplished by spinal circuits consisting of dorsal root afferent and spinal interneurons. Karlsson (1999), however, points out that the underlying pathogenic mechanisms may not be as simple as they first appear. The amplitude of the blood pressure reaction indicates involvement of a large vascular bed, perhaps larger than that of the skin and skeletal muscle. It may be that the splanchnic vascular bed is involved as well, either from the standpoint of active vasoconstriction or simply from a lack of the ability to exhibit compensatory vasodilatation. Afferent and efferent plasticity in the sympathetic nervous system (SNS) may also be involved.

Urodynamic evaluation continues to be a critical component of the evaluation of the LUT in SCI; however, it can incite autonomic dysreflexia. A study of 120 patients with suprasacral SCI undergoing urodynamics assessed the incidence of autonomic dysreflexia (defined as systolic blood pressure increase of 20 mm Hg or more); 42.6% of patients with injuries at T6 or above met criteria for the diagnosis of autonomic dysreflexia. Overall, 36.7% of patients experienced this condition. Surprisingly, 15.4% of patients with lesions below T6 experienced blood pressure elevations. Significant blood pressure increases were more commonly associated with DSD occurring continuously during bladder filling or in individuals with severely impaired bladder compliance as compared with individuals without those two variables. Most patients in this trial (75%) did not experience significant pulse rate changes (10 beats per minute), and, surprisingly, only 22.7% of those with the diagnosis of autonomic dysreflexia actually experienced bradycardia. The finding of dysreflexia in patients with lesions below the classically defined T6 level serves as a signal for close surveillance of SCI patients receiving LUT evaluation (Huang et al., 2011).

Ideally, any endoscopic procedure in susceptible patients should be done using spinal anesthesia or carefully monitored general anesthesia. The hemodynamic effects of this syndrome may be managed with β-adrenergic and/or α-adrenergic blocking agents. Ganglionic blockers were once the mainstay of treatment (Wein, 2002a), but their usage has essentially been abandoned. Sublingual nifedipine is capable of alleviating this syndrome when given during cystoscopy (10 to 20 mg) and of preventing it when given orally 30 minutes before cystoscopy (10 mg) (Dykstra et al., 1987). The rationale for giving this medicine was that smooth muscle contraction would be prevented through its calcium antagonist properties, and the increase in peripheral vascular resistance normally seen with sympathetic stimulation would likewise be prevented. Before electroejaculation, Steinberger et al. (1990) recommended oral prophylaxis with 20 mg of nifedipine, finding this markedly lowered pressure rises during treatment. The use of sublingual nifedipine, however, has been prohibited in many medical centers. Other rapidly acting agents have been reported to be beneficial, and labetalol is recommended by many anesthesiologists (Bycroft et al., 2005). Captopril, hydralazine, and diazoxide are still occasionally recommended but may be less advantageous (Furlan, 2013). **The current recommendation for the acute pharmacologic treatment of autonomic dysreflexia is placement of 2% nitroglycerin paste above the level of the lesion for rapid blood pressure reduction secondary to vasodilation** (Eldahan and Rabchevsky, 2017). Nitrites induce smooth muscle relaxation via conversion to nitric oxide. In instances of persistent hypertension despite transdermal or sublingual nitroglycerin, intravenous nitroprusside may be used. **Pharmacologic treatment should be initiated only after removal of the stimulus (i.e., bladder distention).**

Medical prevention of autonomic dysreflexia has also been examined. Chancellor et al. (1994) reported on the use of terazosin (a selective α_1-adrenergic blocker) for long-term management (3-month study) and prophylaxis of autonomic hyperreflexia. A nightly dose of 5 mg reduced severity, whereas erectile function and blood pressure were unchanged. Vaidyanathan et al. (1998) confirmed the success of prophylactic terazosin. They treated 18 tetraplegic adults and 3 paraplegics with gradually increasing doses of the drug, ultimately varying from 1 to 10 mg daily. The authors reported complete resolution of dysreflexic symptoms in all patients; only 1 tetraplegic patient required drug discontinuation because of persistent dizziness. Such prophylaxis may be particularly important in view of the fact that significant elevations in blood pressure can occur without other symptoms of autonomic hyperreflexia (Linsenmeyer et al., 1996).

Similar salubrious results have been reported with prazosin as prophylaxis for this condition (Bycroft et al., 2005). Prophylaxis, however, does not eliminate the need for careful monitoring during provocative procedures. There are patients with severe dysreflexia that is intractable to oral prophylaxis and correction by urologic procedures. For these unfortunate individuals, a number of neurologic ablative procedures have been used: sympathectomy, sacral neurectomy, sacral rhizotomy, cordectomy, and dorsal root ganglionectomy (Trop and Bennett, 1991). Hohenfellner et al. (2001) advocate sacral bladder denervation by sacral rhizotomy as a moderately invasive, relatively low risk procedure that, along with intermittent catheterization, produces good results in refractory patients.

Vesicoureteral Reflux

The reported incidence of vesicoureteral reflux (VUR) in patients with SCI varies between 17% and 25% (Thomas and Lucas, 1990), **and the condition is more common in those with suprasacral SCI. Contributing factors include (1) elevated intravesical pressure during filling and emptying and (2) infection. Persistent reflux can lead to chronic renal damage and may be an important factor in the long-term survival of patients with SCI.** Hackler et al. (1965) reported that persistent reflux was present in 60% of patients with SCI dying of renal disease. In patients with only transient VUR over a 5- to 15-year period, urography was normal or minimally changed in 83%. High storage and voiding pressures irrespective of VUR can be responsible for renal damage (McGuire, 1984; Vega and Pascual, 2001). Ku et al. (2005) reported on 179 men with SCI at a mean follow-up after injury of 29 years. The incidence of VUR in this group was 15.1%, whereas 34% of patients were diagnosed with pyelonephritis at some point during their follow-up. Nearly 25% developed renal stones, and 32% experienced upper tract deterioration as manifested by hydronephrosis. Upper tract degeneration was more prevalent in those managed with urethral catheters (51%) than in those managed with either spontaneous voiding or CIC. Urethral catheter drainage was inferior to all other forms of bladder drainage in terms of protecting the upper tracts, underscoring the inadvisability of chronic urethral catheterization in this patient population (Ku et al., 2005).

The best initial treatment for VUR in a patient with voiding dysfunction

secondary to neurologic disease or injury is to normalize LUT urodynamics (i.e., decrease storage pressures and decrease outlet resistance). Depending on the clinical circumstances, this may be achieved by pharmacotherapy, urethral dilatation (in the myelomeningocele patient), neuromodulation, deafferentation, augmentation cystoplasty, or sphincterotomy (Flood et al., 1994; Perkash et al., 1998). If this fails, the question of whether to operate on such patients for correction of the reflux or to correct the reflux while performing another procedure (e.g., augmentation cystoplasty) is not an easy one, because correction of reflux in a frequently very thickened bladder may not be an easy task.

Transureteroureterostomy for unilateral reflux is feasible, but even experienced urologists have had difficulties with ureteral calculi trapping, recurrent VUR, and obstruction at the vesicoureteral junction after such procedures in this difficult group of patients (Van Arsdalen and Hackler, 1983). Submucosal trigonal injection of bulking substances has added a new dimension to the treatment of this difficult problem. Despite increased awareness of renal dysfunction related to high-pressure reflux in the SCI population, the prevalence of renal functional compromise in this population remains significant (Fischer et al., 2012).

Occasionally, bladder neck closure and permanent suprapubic drainage are indicated in the case of the severely dysfunctional or destroyed urethra arising from long-term indwelling catheterization (Colli and Lloyd, 2011). Urinary diversion continues to be a common method for management of LUT complications in this patient population (Peterson et al., 2012). However, in some cases, alternative diversion techniques using detubularized bowel segments may be successful (Khavari et al., 2012).

Finally, clinicians must remember the potential artifact that significant reflux can introduce into urodynamic studies. **Measured bladder capacity appears artifactually large, and measured pressures at given inflow volumes may appear lower than those after reflux correction.** The apparent significance of detrusor overactivity may thus be underestimated.

Urinary Tract Infection

UTI is relatively common in patients with SCI and occurred in 100% of patients with SCI in one study with 40- to 50-year follow-up (Gao et al., 2017). UTI or bacteriuria may occur in up to 57% of patients with SCI in the first year after initial hospitalization (Morton et al., 2002). Identified risk factors for UTI include male gender, cervical-level of injury, and condom catheter use (Gao et al., 2017). Recurrent infections may be a manifestation of upper or lower tract calculi, symptomatic or silent pyelonephritis, or LUT dysfunction causing persistently elevated residual urine. In conjunction with poor urodynamic function, UTI can lead to high morbidity, poor quality of life, and decreased life expectancy in patients with SCI (Sauerwein, 2002). The use of antibiotics in SCI patients remains a topic of controversy. **A consensus reached by the National Institute on Disability and Rehabilitation Research Group in 1992 stated that bacteriuria should be treated only when the patient has signs or symptoms of a UTI** (Penders et al., 2003). Although several years old, this comprehensive review by Biering-Sorensen et al. (2001) recommended the following, which remain true in the management of bacteriuria and UTIs:

1. Treat bacteriuria only if symptomatic.
2. Use antimicrobial agents, if possible, with little or no impact on normal flora.
3. Treat at least 5 days, and 7 to 14 days for those with reinfection or relapse.
4. Repair structural and functional risk factors.
5. Use prophylaxis only in those with recurrent UTI when no underlying cause can be found and especially in those patients with dilated upper tracts.
6. Do not use antibiotics to prevent UTI in patients with an indwelling catheter or intermittent catheterization.

The role of catheter type and infection risk has been assessed extensively, with evidence supporting the use of hydrophilic catheters (Bermingham et al., 2013; Li et al., 2013). There have been conflicting studies about the use of prophylactic antibiotics in patients with recurrent UTIs and/or the need for catheterization (Morton et al., 2002; Sauerwein 2002) and in truth, there are few evidence-based data in this area (Hooton et al., 2010). In a recent initiative, the American Board of Internal Medicine partnered with the American Urological Association to create recommendations for the **Choosing Wisely campaign, which recommends against the prescription of antibiotics for patients using indwelling or intermittent catheterization in the absence of signs and symptoms of a UTI (www.choosingwisely.org)**.

Spinal Cord Injury in Women

There are many aspects of management of the LUT affected by SCI that are specific to women (Yang and Cardenas, 2001). The body composition of women with SCI shows deficient protein and bone mass and excess fat, predisposing them to an increased risk of skin breakdown and incidence of fractures, a finding compounded by osteoporosis. The symptoms of menopause (e.g., hot flashes) may be difficult to distinguish from those of autonomic dysreflexia, and incontinence and UTIs worsen with age in women in the general population and particularly in those with SCI (Kalpakjian et al., 2010).

Suitable bladder reservoir function can usually be achieved either pharmacologically or surgically, and paraplegic women can usually master CIC. However, special difficulty is encountered in these patients because of the lack of an appropriate external collecting device. Although some tetraplegic women can be trained to perform CIC, there is no practical alternative to indwelling catheterization for most (Lindan et al., 1987). There are reports of long-term drainage with an indwelling urethral catheter being well tolerated; however, McGuire and Savastano (1986) point out the potential for significant incontinence around the catheter and the development of upper tract changes (Kalpakjian et al., 2010).

For those female patients with SCI who can perform CIC or who have around-the-clock medical or family care, creation of adequate bladder reservoir function is reasonable. For those not in this category, the alternatives are limited and challenging. Bennett et al. (1995) compared the incidence of major complications in a group of female patients with SCI who were managed long term by (1) CIC; (2) reflex voiding and incontinence padding; and (3) an indwelling catheter. There were 10 major complications in the 25 patients in group 2, 58 in the 22 patients in group 3, and only 4 major complications in group 1. Singh and Thomas (1997) looked at the results of treatment in a group of female tetraplegics. Twenty-three of 27 patients with complete lesions wound up using an indwelling catheter, 3 underwent diversion, and in 1 patient the caregiver performed CIC. In 20 patients with incomplete lesions, all with poor functional recovery, 14 had permanent indwelling catheters, 3 were able to perform CIC, and 3 used reflex voiding by triggering. Of 37 patients with incomplete lesions with good functional recovery, only 3 required indwelling catheterization, 4 used CIC, and most were able to use reflex voiding by triggering. The authors noted also that 55% of the women with permanent catheters had bladder calculi, 35% had leakage around the catheter, and 33% had recurrent symptomatic infection. Although upper tract changes were seen in only

5%, it is obvious that the authors consider that, for the most part, female patients with voiding dysfunction secondary to cervical SCI who exhibit poor functional recovery represent urologic failures of management. Surgical intervention for stress urinary incontinence in this population also may be beneficial in well-selected patients. Mid-urethral tapes have been reported to produce reasonable outcomes in selected women with SCI (Pannek, 2012). Other groups have reported durable and safe results using autologous tissue as the sling type (Athanasopoulos et al., 2012).

Spinal Cord Injury (Neurogenic Bladder) and Bladder Cancer

There is a strong association between the development of bladder cancer and long-term indwelling catheterization. Kaufman et al. (1977) initially reported squamous cell carcinoma of the bladder in 6 of 59 patients with SCI who had long-term indwelling catheters. Four of these patients had no obvious tumors visible at endoscopy, and the diagnosis was made by bladder biopsy. Five of these patients also had transitional cell elements in their tumor. Broecker et al. (1981) surveyed 81 consecutive SCI patients with an indwelling urinary catheter for more than 10 years, and, although the investigators did not find frank carcinoma in any patient, they found squamous metaplasia of the bladder in 11 and leukoplakia in 1. Locke et al. (1985) noted 2 cases of squamous cell carcinoma of the bladder in 25 consecutive SCI patients catheterized for a minimum of 10 years. Bickel et al. (1991) reported 8 cases of bladder cancer in men with SCI, although the denominator was uncertain. Four of the men had been managed by indwelling catheterization for 7, 10, 14, and 19 years, respectively. All of these 4 had transitional cell carcinoma, whereas in the other 4 men there were 2 cases of transitional and 2 of squamous cell carcinoma. In a series by Chao et al. (1993), 6 patients developed bladder cancer, 3 of whom had indwelling catheters (of a total of 32) and 3 of whom (of 41) did not. Stonehill et al. (1996) retrospectively reviewed all bladder tumors in their SCI patients for 7 years and compared these with matched controls. They found 17 malignant and 2 benign bladder tumors; indwelling catheter and a history of bladder calculi were statistically significant risk factors.

Hess et al. (2003) reported their own series and summarized one view of the literature regarding SCI and bladder cancer: (1) the relative risk in SCI patients is 16% to 28% greater than the general population; (2) the overall incidence is 2.3% to 10%; (3) there is a higher proportion of squamous cell than transitional cell carcinoma; (4) the prevalence peaks at an earlier age than in the general population; (5) diagnosis is often made at a more advanced stage; (6) risk factors include chronic indwelling catheterization, bladder stones, and chronic UTI; (7) neither cystoscopy nor cytology is an entirely reliable diagnostic tool; and (8) those with multiple risk factors should have a more aggressive evaluation.

There is not agreement of the utility of cystoscopy and cytology in the screening and diagnosis of bladder cancer in neurogenic bladder. Pannek et al. (2017) reported that cystoscopy and cytology in combination can improve bladder tumor detection. Conversely, Alimi et al. (2018) in a systematic literature search concluded there were insufficient data to definitively recommend using cytology and cystoscopy in the screening of bladder cancer. Despite the paucity of data, cystology and cystoscopy remain the principal tools in screening for bladder cancer in this population.

Tempering these views are reports by Pannek (2002), who reviewed the data from 43,561 patients with SCI in three countries and concluded that the incidence of bladder cancer is comparable with that of the general population. However, more than 60% of those affected had muscle invasive disease on initial presentation. Chronic indwelling catheters and persistent or recurrent UTI are suggested as risk factors rather than the SCI. Subramonian et al. (2004), in an assessment of spina bifida patients, reported similar conclusions regarding age-standardized incidence of bladder cancer relative to the general population. They reported a lifetime risk of 2.4% in their reported population. This compares with a lifetime risk estimation of 30.7 to 720 per 100,000. Seventy-five percent of the affected patients in the series had indwelling catheters for 18 to 32 years.

Whether the incidence of bladder cancer is increased or not in the SCI population, the natural history of bladder cancer is thought to be more highly aggressive in neurogenic patients and is responsible for 0.3% to 2.8% of known deaths in the SCI population. A recent meta-analysis by Ismail et al. (2017) demonstrated a 0.3% incidence of bladder cancer in patients with neurogenic bladder. The majority of the patients had SCI (99%), and 44.5% of patients had an indwelling catheter. Transitional cell carcinoma was the most common histology, but the tumors were more likely to be muscle invasive, which is a contributing factor to the higher mortality rate seen compared with the general population.

Follow-Up

With advances in medical and surgical care, mortality of SCI patients has decreased over time, resulting in a greater need for meticulous long-term urologic follow-up. In a cohort of SCI patients with 40 to 50 years follow-up (Gao et al., 2017), all patients experienced at least one UTI; however, on average, patients experienced 48.6 UTI episodes. Other than UTI, the most common complications were bladder stones in 49%, hydronephrosis in 47%, and VUR in 33%. Less common, but still problematic, complications included pyelonephritis, autonomic dysreflexia, urethral injury, and urosepsis. **The complexity of these patients, and the high likelihood of complications, highlights the necessity of lifelong urologic follow-up.**

Linsenmeyer and Culkin (1999) reported the American Paraplegia Society (APS) guidelines for urologic care of SCI. **Annual follow-up is recommended for the first 5 to 10 years after injury, and if the patient is doing well, then follow-up every other year is advised. Upper and lower tract evaluation should be done initially, yearly for 5 to 10 years, and then every other year.** Burns et al. (2001) recommended at least plain films and nuclear renal scans, with a decrease of more than 20% in renal plasma flow warranting further investigation. **Urodynamic evaluation was recommended by the APS at the same intervals as upper and lower tract screening. Cystoscopy was recommended annually in those with an indwelling catheter.**

In 2006 the Consortium for Spinal Cord Medicine detailed a set of guidelines for bladder management in adults with SCI and stated that, in general, a urologic evaluation should be done yearly, although no studies exist on the optimum frequency of such examinations or the tests that should be included (Consortium for Spinal Cord Medicine, 2006).

The European Association of Urology (EAU) guidelines for follow-up of all neurogenic LUT dysfunctions call for meticulous and regular re-evaluations at intervals of no more than 1 to 2 years, and more frequently for patients with MS and acute SCI and other unstable conditions. They include the following guidelines:

1. Supply the patient with urinary dipsticks to check the urine at least every 2 months and whenever a urinary infection is suspected.
2. Perform upper urinary tract and bladder morphology every 6 months (ultrasonography), along with residual urine determination.
3. Conduct physical examinations and blood chemistries yearly.
4. Obtain detailed specialist investigation every 1 to 2 years and on demand when risk factors emerge (Pannek et al., 2011).

Cervical Myelopathy

Cervical myelopathy is usually caused by compression, secondary to spondylosis, ossification of the posterior longitudinal ligament, or cervical disk herniation (Mochida et al., 1996; Sakakibara et al., 1995a). Sakakibara et al. (1995a) studied 128 affected patients, of whom 95 had voiding symptoms, 61 had storage symptoms, 71 had obstructive symptoms, and 25 had urinary incontinence. Urodynamic studies revealed detrusor overactivity in 61 patients and DSD in 22. On the other hand, Mochida et al. (1996) reported that 22 of 60 (37%) patients undergoing surgery for cervical myelopathy were found to have neuropathic bladder dysfunction on urodynamic evaluation. Of these, 9 (41%) were found to have detrusor overactivity, but 13 (59%) were characterized as having an underactive detrusor. These findings are at odds with what is expected with only cervical spinal cord pathology; therefore the need for urodynamic study to optimally guide therapy in patients with neurogenic bladder is reinforced.

Acute Transverse Myelitis

Acute transverse myelitis is a rapidly developing condition with motor, sensory, and sphincter abnormalities, usually with a well-defined upper sensory limit and no signs of spinal cord compression or other neurologic disease (Kalita et al., 2002). It may result from a variety of mechanisms—parainfectious, autoimmune, vascular, or demyelinating (Ganesan and Borzyskowski, 2001). The condition usually stabilizes within 2 to 4 weeks and is not progressive afterward; however, recovery may be variable and some residual neurologic deficits are possible. Although recovery is more variable, and the prognosis, in general, is more favorable, the development and nature of voiding dysfunction have been reported to be similar, level by level, to those of SCI (Sakakibara et al., 1995b). Kalita et al. (2002) reported on 18 patients with acute transverse myelitis whose 6-month outcome included persistent retention in 6 and storage symptoms in 10, of whom 5 had emptying problems as well. Only 2 patients had regained normal voiding. In the acute state, urodynamics showed an areflexic or contractile bladder in 10, detrusor overactivity with poor compliance in 2, and DSD in 3. Seventeen had urinary retention on presentation. More recently, Gupta et al. (2017) performed urodynamic studies in 43 patients after recovery from the spinal shock phase. The majority (86%) had detrusor overactivity, and 20 patients had dyssynergia. Five patients had detrusor underactivity, and 1 patient had a normal study. There was no identifiable pattern correlating severity of disease with urodynamic findings. As in SCI, urodynamic studies in patients with acute transverse myelitis are necessary to guide irreversible therapy because the activity of the bladder and outlet during storage and emptying does not always correspond to the expected pattern based on the level of pathology.

Neurospinal Dysraphism

Neurospinal dysraphism is the malformation of the vertebral arches and, commonly, malformation of the neural tube. The term includes spina bifida occulta, which involves only a bony (vertebral) arch defect; and spina bifida cystica (aperta), which involves a bony defect and a neural tube (spinal cord) defect. The two primary subclasses of spina bifida cystica are myelomeningocele (the nerve roots or portions of the spinal cord have evaginated beyond the vertebral bodies) and meningoceles (which contain only a herniated meningeal sac with no neural elements). If fatty tissue is present in the sac in either case, the prefix *lipo*- is added (Churchill et al., 2001). **Myelomeningocele accounts for more than 90% of spina bifida cystica and is the most devastating condition in terms of sequelae. Of myelomeningoceles, 2% are cervical, 5% thoracic, 26% lumbar, 47% lumbosacral, and 20% sacral. The level(s) of the lesion correlate(s) poorly with urodynamic findings** (Churchill et al., 2001). **Myelomeningocele occurs in approximately 1 per 1000 live births** (Drake et al., 2013; Wyndaele et al., 2005). **The incidence of LUT dysfunction is not absolutely documented, but most studies suggest an incidence of more than 90%** (Drake et al., 2013, Liu et al., 2018; Wyndaele et al., 2005). The incidence of spina bifida has decreased in recent years because of the recognition of the importance of folate ingestion in pregnant women and advanced prenatal diagnostic capabilities resulting in selective termination of pregnancies. However, up to 85% of patients with spina bifida do survive to adulthood; therefore this condition is becoming a more significant chronic care issue in the general population. Transitional care from childhood through adolescence to adulthood is becoming a focus of specialized clinics despite the fact that many barriers do exist (Summers et al., 2014).

McGuire and Denil (1991) and Woodhouse (2005) point out that, because of progress in the overall care of children with myelodysplasia, urologic dysfunction often becomes a problem of the adolescent or adult with this disease. In McGuire and Denil's (1991) experience, **the "typical" myelodysplastic patient shows an areflexic bladder with an open bladder neck. The bladder usually fills until the resting residual fixed external sphincter pressure is reached, and then leakage occurs. Stress incontinence may also occur** because of changes in intra-abdominal pressure. A small percentage (10% to 15%) of patients demonstrate DSD, but these individuals show normal bladder neck function that, if detrusor reflex activity is controlled, may be associated with urinary continence. After puberty, most authors report that the majority of myelodysplastic patients note an improvement in continence, but at that age and afterward they are less inclined than children to tolerate any degree of incontinence. In adult patients, the problems encountered in myelodysplastic children still exist but are often compounded by prior surgery, upper tract dysfunction, and one form of urinary diversion or another.

Perhaps the most important intervention for myelomeningocele is amelioration of the initial impact of the disease. **A prenatal intervention trial was discontinued before study completion when the primary outcome of fetal or neonatal death or the need for cerebrospinal fluid shunt by age of 12 months was substantially less in the treated group** (Adzick et al., 2011). An additional primary outcome of overall mental development and motor function at age 30 months showed that in individuals undergoing prenatal surgery, substantial improvement was encountered as compared with those receiving only postnatal interventions. In the prenatal surgery group, 40% of patients required cerebrospinal fluid shunts, whereas 82% of those in the postnatal group did. In addition, highly significant improvement in motor function and mental development was noted in the prenatal as compared with the postnatal group. A variety of secondary outcomes also were improved in this group, including the risk of hindbrain herniation at 12 months and ambulation by 30 months. However, there was an increased risk of preterm delivery and uterine dehiscence at delivery in the prenatal group as compared with the postnatal group. In terms of the lower urinary tract, there was no difference in intermittent catheterization rates between the prenatal and postnatal groups, but those patients undergoing prenatal surgery has less bladder trabeculation and less likely to have an open bladder neck (Brock et al., 2015). The significance of these findings on the lower urinary tract remains unclear; nonetheless, this randomized trial of prenatal versus postnatal repair showed significant benefits to prenatal repair, resulting in termination of this trial on elevation of this intervention to a primary consideration for the condition of prenatally diagnosed myelomeningocele

(Adzick et al., 2011).

Nowhere is the failure of a neurologic examination to predict urodynamic behavior more obvious than in patients with myelomeningocele. van Gool et al. (2001) categorized the urodynamic findings in 188 children with myelomeningocele into five groups: (1) normal detrusor and sphincter activity (7%); (2) detrusor overactivity and an inactive sphincter (11%); (3) detrusor overactivity and an overactive sphincter (45%); (4) inactive detrusor and inactive sphincter (23%); and (5) an inactive detrusor and an overactive sphincter (14%). In 16 adults with myelomeningocele, Sakakibara et al. (2003a) reported detrusor overactivity in 38%, low compliance in 81%, impaired bladder sensation in 25%, DSD in 50%, low maximum urethral pressure in 56%, and silent sphincter electromyographic findings in 25%. Webster et al. (1986) reported that 62% of their patients with myelomeningocele had detrusor overactivity, whereas 38% had detrusor areflexia. Thirty of 34 patients in the latter group had low compliance with high terminal filling pressures. Striated sphincter behavior was characterized as follows: true DSD in 15%, an apparently innervated but fixed nonrelaxing sphincter in 15%, and some evidence of striated sphincter denervation in 69%. **Regardless of the pattern of LUT dysfunction in the adult, the main goal of therapy is the avoidance of high storage pressures** (McGuire and Denil, 1991; Persun et al., 1999; Woodhouse, 2005).

LUT dysfunction secondary to occult spinal dysraphism may not manifest in childhood, and such patients may be referred as adults for symptoms as commonplace as urinary incontinence or recurrent UTIs. Delayed diagnosis of such voiding dysfunction has been reported by several authors (Jakobsen et al., 1985; Yip et al., 1985). **The treatment strategy in women is to increase urethral sphincter efficiency without causing an increase in urethral closing pressure significant enough to result in a change in bladder compliance** (McGuire and Denil, 1991). **Periurethral injection therapy may be a safer option than the pubovaginal sling and artificial urethral sphincter in this case. Stress incontinence in men with myelodysplasia may follow similar general rules as in women, and bulking agents may give good results in this group as well. When the urethra is very widely dilated and somewhat rigid, and neither procedure alone provides sufficient coaptation, it may be possible to combine a “prostatic sling” with periurethral bulking.** Ongoing trials using stem cells in the treatment of stress incontinence in women and treatment of post-prostatectomy incontinence in men may one day translate into treatment options for the neurogenic population. **Continent individuals will**

remain on CIC.

The urologic rehabilitation of patients with spinal dysraphism relies primarily on medical management and intravesical injection of onabotulinumtoxinA, with the selective use of augmentation enterocystoplasty or urinary diversion if failure occurs. However, surgery does not necessarily yield superior results. In a review of 421 patients managed for complications relating to spina bifida, 45% were treated medically, either with CIC, spontaneous voiding, or no specific method, and 55% were treated surgically. Overall incontinence episodes were higher in the surgical management group; however, these outcomes may have been reflective of the aggressiveness of management as well as the severity of disease (Lemelle et al., 2006). A recent evaluation of individuals being followed long term for myelomeningocele (20-year follow-up) found that 7 patients (13% of the original 52 followed) had unilateral renal dysfunction and 8 (15%) had bilateral overall renal dysfunction. Those with bilateral dysfunction had a significantly higher risk of detrusor overactivity during childhood urodynamic evaluation (63%) compared with those with normal function (24%). Overall, 48% of patients were continent at follow-up. Eight patients required surgical intervention sometime during the course of their condition. Nine used regular antimuscarinic ingestion, and 3 had had intravesical botulinum toxin injection. In addition, 27 required intermittent catheterization for management. Therefore urodynamic findings may be predictive of long-term consequences (Thorup et al., 2011). Surgery remains a salvage option for those not optimally managed by medical intervention. An assessment of national data practices using administrative data sets from a nationwide inpatient sample assessed patients undergoing bladder augmentation versus ileal conduit urinary diversion over a 7-year timeframe (1998 to 2005) for the primary diagnosis of spina bifida. Overall, 3403 patients underwent bladder augmentation, whereas 772 underwent ileal loop diversion. The bladder augmentation group tended to be younger patients (16 vs. 36 years) and more commonly male (52%). Urinary diversion was more commonly associated with the female patients as well as older patients. Overall, those undergoing urinary diversion had higher health care expenses and longer hospital stays. There was some difference in care choice based on insurance status (Wiener et al., 2011).

Neural rerouting has been proposed as a potential option for some of these individuals. Xiao et al. (2005) have performed microanastomosis of the fifth lumbar ventral root to the third sacral ventral root to bypass low-level spina bifida injury. Initial improvements in bladder compliance and urinary incontinence were noted in patients and paralleled similar findings in patients with SCI (Joseph, 2005). In a small randomized trial comparing spinal cord detethering alone with detethering plus the Xiao procedure (nerve transfer procedure) found greater improvements in bladder capacity and bladder overactivity, although no difference in continence rates, in the group undergoing detethering plus the Xiao procedure (Tuite et al., 2016).

Tethered cord syndrome (TCS) is defined as a stretch-induced functional disorder of the spinal cord with its caudal part anchored by inelastic structures and restricting vertical movement. The anchoring structures can include scar from prior surgery, fibrous or fibroadipose filum terminale, a bony septum, or tumor (Yamada et al., 2004a, 2004b). Adults with TCS can be divided into those with a prior history of spinal dysraphism with a previously stable neurologic status who experience subtle progression in adulthood and those without associated spinal dysraphism who present with new-onset subtle neurologic symptoms (Yamada et al., 2004a, 2004b). **Symptoms can include back pain, leg weakness, foot deformity, scoliosis, sensory loss, and bowel or LUT dysfunction** (Phuong et al., 2002). **TCS is reported to occur in 3% to 15% of patients with myelomeningocele. There is no typical dysfunction in TCS, and treatment must be based on urodynamic evaluation.** LUT dysfunction may not be present until the teenage years or later (Husmann, 1995; Kaplan and Blaivas, 1988). Giddens et al. (1999) point out that, whereas children often develop symptoms of tethered cord after growth spurts, in adults the presenting symptomatology often follows activities that stretch the spine, such as sports or motor vehicle accidents. In adults, urologic presentation can include storage or voiding symptoms, incontinence, or complete retention. In a group of adult patients, urgency (67%) and urgency incontinence (50%) were the most common findings at presentation. Pretreatment urodynamics in 18 patients revealed detrusor overactivity in 72%, DSD in 22%, decreased sensation in 22%, decreased compliance in 17%, and what was termed a “hypocontractile” detrusor in 11%. Postoperative urodynamic findings improved in only 29% and were unchanged in 71%. Steinbok et al. (2007) assessed 8 children undergoing section of the filum that induced the tethered cord and compared them with 7 children who had abnormal urodynamic findings and did not undergo filum release. Clinical improvement occurred in 7 of the 8 children at a mean follow-up of 3 years with improved urodynamics in 4 of 7 children tested after surgery. These improvements were also associated with nonurologic functional improvements (i.e., motor leg function). Two patients in the nonsurgical group had urologic improvement at a mean follow-up of 3 years; however, 3 patients required surgical intervention and 5 had persistence of nonurologic symptoms. Thus section of the cord appeared to improve function as compared with conservative, nonsurgical management.

Not all symptoms of tethered cord are remediated by surgery. In a retrospective assessment of 29 patients undergoing first-time tethered cord release, clinical symptoms were evaluated at 1 and 3 months after surgery as well as every 6 months thereafter. Garces-Ambrossi et al. (2009) addressed rates of improvement in motor and urinary dysfunction over time. The most common causes of tethered cord included lipomyelomeningocele (10%), tight filum (10%), lumbosacral lipoma (14%), intradural tumor (10%), and previous surgery (7%). In addition, 48% of patients had had previous repair of myelomeningocele defects. Symptoms before intervention occurred for a mean of 5 months. Symptomatic presentation included diffuse pain and paresthesias in both lower extremities (45%) or perineum (62%). Lower extremity weakness was noted in patients with gait disturbances (59%) and bladder dysfunction (48%). Multilevel laminectomy accompanied by duraplasty (30% of patients) was performed as the primary intervention. At 18 months postoperatively, 47% of the patients with urinary symptoms had improvement in those symptoms, 69% had improvement in the lower extremity weakness, and 79% had improved painful dysesthesias. Mean time for improvement was 1 month for pain and 2.3 months for motor symptoms. Urinary symptoms lagged at 4.3 months. The majority of patients demonstrated improvement within 6 months of surgery (96%). After 1 year, only 4% showed no improvement (Garces-Ambrossi et al., 2009).

Recent emphasis on transitional aspects of care from childhood to adulthood has centered on the need for meticulous follow-up and optimization of bladder and renal function in light of social stigma, patient concerns, independence, and also bowel-related dysfunction. Consensus agreement stresses the need for established algorithmic approaches for follow-up inclusive of annual surveillance for early identification of urinary tract deterioration. These assessments should include renal and bladder ultrasonography and urodynamics when indicated (by symptomatic change or clinical physical examination finding). In addition, serum creatinine and renal scintigraphy may be performed when upper tract changes are suspected. Goals of therapy include reduction in detrusor pressure and maintenance of bladder compliance and social continence (de Kort et al., 2012). Barriers to young adults transitioning from pediatric to adult care must be considered and addressed, and often a multidisciplinary approach is necessary (Grimsby et al., 2016). Lifelong urologic follow-up is mandatory.

Tabes Dorsalis, Pernicious Anemia

Although tabes dorsalis, also known as syphilitic myelopathy, is rapidly disappearing as a major neurologic problem, involvement of the spinal cord dorsal columns and posterior sacral roots can result in a loss of bladder sensation and large postvoid residual urine volumes and therefore can be a cause of "sensory neurogenic bladder." Although this represents the classic tabetic bladder (Wheeler et al., 1986), Hattori et al. (1990) reported on some patients with only tabes dorsalis as an obvious cause of their LUT dysfunction who had low compliance or detrusor overactivity. Another spinal cord cause of the classic "sensory bladder" is pernicious anemia, a disease caused by impaired uptake of vitamin B_{12} resulting from the lack of intrinsic factor in the gastric mucosa. Pernicious anemia is closely associated with subacute combined degeneration (SACD) of the dorsolateral columns of the spinal cord with common pathophysiology of vitamin B12 deficiency.

Subacute Combined Degeneration

SACD is demyelination of the posterior and lateral columns of the spinal cord resulting most commonly from vitamin B12 deficiency but can also be a result of copper deficiency. Vitamin B12 deficiency is associated with deficient dietary intake (vegetarianism and old age), gut malabsorption, gastrectomy, fish tapeworm infestation, and autoimmune disorders. In a study of eight patients with this condition, multiple nonurologic symptoms were associated with the condition, including ambulation problems in addition to joint spasticity. Urinary symptoms represented a mix of storage (five of eight patients), voiding (seven of eight patients), and combined dysfunctions (four of eight patients). Urodynamic evaluation revealed detrusor areflexia in two patients, NDO in three, and normal studies in the remainder. After treatment with vitamin B_{12} supplementation, detrusor areflexia improved in two patients, dysfunction improved in three patients completely, and four had partial recovery (Misra et al., 2008). Typical MRI findings include T2 hyperintensity in the posterior spinal column and subcortical white matter defects.

Poliomyelitis

Although not always present, when voiding dysfunction is seen in patients with polio, it is that of a typical “motor neurogenic bladder” with urinary retention, detrusor areflexia, and intact sensation. The reported incidence of LUT dysfunction in patients with polio was described as ranging from 4% to 42% by Bors and Comarr (1971). A study describing bladder symptoms among polio survivors found that urinary hesitancy, weak stream, incomplete emptying, nocturia, and urge incontinence occurred with higher frequency in polio survivors compared with the normal population (Kay and Bertelsen, 2013).

Disease Distal to the Spinal Cord

Disk Disease

Goldman and Appell (2000a, 2000b) nicely summarize the anatomic and neurologic considerations applicable to voiding dysfunction from lumbar disk disease. **In the adult, the sacral segments of the spinal cord are at the level of the L1 and L2 vertebral bodies.** In this distal end of the spinal cord **(conus medullaris),** the spinal cord segments are named for the vertebral body at which the nerve roots exit the spinal canal. Thus, although the sacral spinal cord segment is located at vertebral segment L1, its nerve roots run in the subarachnoid space posterior to the L2 to L5 vertebral bodies until reaching the S1 vertebral body, at which point they exit the canal. Therefore all of the sacral nerves that originate at the L1 and L2 spinal column levels run posterior to the lumbar vertebral bodies until they reach their appropriate site of exit from the spinal canal. This group of nerve roots running at the distal end of the spinal cord is commonly referred to as the ***cauda equina.***

Usually, disk prolapse is in a posterolateral direction, which does not affect the majority of the cauda equina. However, in 1% to 15% of the cases (Goldman and Appell, 2000b), central disk prolapse occurs and compression of the cauda equina may result. Thus disk prolapse anywhere in the lumbar spine could interfere with the parasympathetic and somatic innervation of the LUT, striated sphincter, and other pelvic floor musculature, and afferent activity from the bladder and affected somatic segments to the spinal cord. **Most disk protrusions compress the spinal roots in the L4 to L5 or L5 to S1 vertebral interspaces. When LUT dysfunction is present, it typically occurs with the usual clinical manifestations of low back pain radiating in a girdle-like fashion along the involved spinal root areas. The most characteristic findings on physical examination are sensory loss in the perineum or perianal area (S2 to S4 dermatomes), sensory loss on the lateral foot (S1 to S2 dermatomes), or both.**

A review of the literature on LUT dysfunction associated with lumbar disk disease found that the incidence ranged from 27% to 68%; however, the true incidence is unknown because many series describe findings only in patients with LUT dysfunction (Siracusa et al., 2013). Bartolin et al. (1998) found detrusor areflexia in 27% and normal detrusor activity in the remaining 73% of

114 patients with lumbar disk protrusion. **All 31 patients with detrusor areflexia reported difficulty voiding with straining, and patients with voiding dysfunction generally presented with these symptoms or in urinary retention. The most consistent urodynamic finding was that of a normally compliant areflexic bladder associated with normal innervation or findings of incomplete denervation of the perineal floor musculature.** In a later report, Bartolin et al. (2002) described findings in 122 patients with lumbar disk protrusion. Detrusor areflexia was found in 32 (26%) and normal bladder urodynamic findings in 90 (74%). All with areflexia complained of difficulty voiding; 8 could not void at all, 14 had an interrupted flow, and 10 had a continuous but low flow. Occasionally, patients may show detrusor overactivity attributed to irritation of the nerve roots (O'Flynn et al., 1992).

The detrusor areflexia associated with lumbar disk protrusion shows a lower incidence of concomitant decreased compliance than in the voiding dysfunction associated with myelomeningocele. Sandri et al. (1987) offered two possible explanations for this difference: (1) the effect of the disk represents a more incomplete lesion of the preganglionic parasympathetic fibers and (2) the lesion is more sensory than motor, implying that the decreased compliance seen with the type of neural lesion in myelomeningocele is caused primarily by injury of the preganglionic parasympathetic motor fibers to the bladder.

Laminectomy may not improve LUT function in many cases, and pre-laminectomy urodynamic evaluation is prudent because it may be difficult postoperatively to separate causation of voiding dysfunction resulting from the disk sequelae from changes secondary to the surgery. In a group of patients with lumbar disk protrusion who underwent corrective surgery, Bartolin et al. (1999) reported that detrusor activity returned to normal in only 6 of 27 patients with preoperative detrusor areflexia. Of the 71 patients with normal urodynamic findings preoperatively, 4 developed detrusor overactivity and 3 developed postoperative detrusor areflexia. Although there are several reasons to explain this finding, such as recurrence of nerve compression, worsening of the original disease process, or iatrogenic cause from surgery, it is clear that patients undergoing lumbosacral spinal surgery are at risk for postoperative urinary dysfunction, and the medicolegal implications of a presurgical and postsurgical urodynamic evaluation are obvious.

***Cauda equina syndrome* is a term applied to the clinical picture of perineal sensory loss with loss of voluntary control of anal and urethral sphincter and of sexual responsiveness.** The clinical picture in cauda equina syndrome can vary widely, from minimal to maximal sensory and motor involvement. This can occur secondary to not only disk disease (severe central posterior disk protrusion) but also other pathological processes affecting the spinal canal. Yamanishi et al. (2003) place the incidence of cauda equina syndrome at 1% to 5% of all prolapsed lumbar disks. All eight patients undergoing emergency corrective surgery had an acontractile detrusor with no bladder sensation, and four of seven had an inactive sphincter electromyogram. Follow-up urodynamics showed that all still had an acontractile detrusor and three had normal electromyographic activity. Three patients had electromyographic activity, but with denervation potentials in two and low activity in two. One hypothesis for the finding that electromyographic activity returned while detrusor function remained poor is that recovery of autonomic nerves affecting bladder function may be slower than that of somatic nerves controlling the sphincter.

In the case of cauda equina syndrome, urgent surgical decompression is recommended and can help improve the likelihood of bladder function recovery. In a meta-analysis of surgical outcomes of cauda equina syndrome secondary to lumbar disk herniation, patients undergoing surgery within 48 hours had significantly better resolution of their symptoms, including urinary and rectal incontinence, compared with those undergoing surgery 48 hours or more after the onset of symptoms (Ahn et al., 2000). Overall, of the 322 patients included in the meta-analysis, 73% had urinary continence after surgery. However, despite surgical management of patients with disk herniation, recovery of normal lower urinary tract function is variable.

Spinal Stenosis

Spinal stenosis is a term applied to any narrowing of the spinal canal, nerve root canals, or intervertebral foramina. It may be congenital, developmental, or acquired. Compression of the nerve roots or cord by such a problem may lead to neuronal damage, ischemia, or edema. **Spinal stenosis may occur without disk prolapse. Symptoms may range from those consequent to cervical spinal cord compression to a cauda equina syndrome with corresponding urodynamic findings** (Smith and Woodside, 1988). Back and lower extremity pain, cramping, and paresthesias related to exercise and relieved by rest are the classic symptoms of lumbar stenosis caused by lumbar spondylosis and are believed to result from a sacral nerve root ischemia. The urodynamic findings are dependent on the level and the amount of spinal cord or nerve root damage. Deen et al. (1994) reported subjective improvement in more than 50% of such patients with bladder dysfunction who were treated by decompressive laminectomy. In cervical spondylitic spinal stenosis, detrusor overactivity or underactivity may occur, depending on whether the primary pathological process affecting the micturition neural axis is compression of the inhibitory reticulospinal tracts or myelopathy in the posterior funiculus, which carries proprioceptive sensation (Tammela et al., 1992). Because there is no consistent pattern of dysfunction with any type of spinal stenosis, urodynamic studies again should serve as the cornerstone of therapy. In a study of 26 patients undergoing urodynamic assessment of spinal stenosis preoperatively and postoperatively, substantive improvements were noted in postvoid residual volume, maximal cystometric capacity, and flow rate postoperatively after successful surgical intervention in all patients. Urodynamic evaluation was important from a diagnostic standpoint to identify patients who were experiencing LUT compromise (Cong et al., 2010).

Radical Pelvic Surgery

The inferior hypogastric plexus (pelvic plexus), which innervates the viscera of the pelvic cavity, is a paired structure located on the side of the rectum in males and at the sides of the rectum and vagina in females. LUT dysfunction after pelvic plexus injury occurs most commonly after abdominoperineal resection (APR) and radical hysterectomy. The true incidence of neurogenic vesicourethral dysfunction after various types of pelvic surgery is unknown because there are few prospectively studied series of patients with preoperative and postoperative urodynamic evaluation. **The incidence has been estimated to range from 20% to 68% of patients after APR, 16% to 80% after radical hysterectomy, 20% to 25% after anterior resection, and 10% to 20% after proctocolectomy** (Blaivas and Chancellor, 1995b). These are estimates drawn from past literature, and the current incidence is most likely significantly lower because of the use of nerve-sparing techniques during these types of pelvic procedures. It has been estimated that **the LUT dysfunction remains permanent in 15% to 20% of affected individuals** (McGuire, 1984; Mundy, 1984). The injury may occur from denervation or neurologic decentralization, tethering of the nerves or encasement in scar, direct bladder or urethral trauma, or bladder devascularization. Adjuvant treatment, such as chemotherapy or irradiation, may compound the damage. The type of LUT dysfunction that occurs is dependent on the specific nerves involved, the degree of injury, and any pattern of reinnervation or altered innervation that occurs over time (see the previous section on neuroplasticity). Therapeutic and disease-related effects on pelvic nerves have substantive effects on long-term functional outcomes after treatment for anal-rectal carcinomas. Approximately one-third of patients have some element of urinary tract dysfunction (urinary frequency, urgency, and/or poor detrusor contraction resulting in retention and incomplete emptying). This can be related to surgical, radiotherapeutic, and chemotherapeutic effects. Abdominoperineal resection has the greatest impact on function, most likely because of autonomic nerve injury at time of resection. Other dysfunctions related to sexual activity, ejaculatory dysfunction in men, and vaginal dryness and dyspareunia in women are also commonly associated with the management of this malignancy (Lange and van de Velde, 2011). Parasympathetic decentralization has been reported to lead to a marked increase in adrenergic innervation of the bladder in some experimental models, with the resultant conversion of the usual β (relaxant) response of the bladder body in response to sympathetic stimulation to the α (contractile) effect (Sundin et al., 1977). Literature on the effects of parasympathetic decentralization on neuromorphology and neuropharmacology of the LUT in many animal models is abundant (Wein and Barrett, 1988). Hanno et al. (1988) confirmed that, in the cat model, parasympathetic decentralization does result in adrenergic hyperinnervation of the detrusor but that pelvic plexus neurectomy alone or parasympathetic decentralization plus hypogastric neurectomy yields no detectable increase in adrenergic innervation. In their experimental model, decentralization did result in synaptic reorganization in bladder wall ganglia with new cholinergic excitatory inputs from the hypogastric nerves. Koyanagi was the first to call attention to what he referred to as supersensitivity of the urethra to α-adrenergic stimulation in a similar group of patients with neurologic decentralization of the LUT, implying a similar change in adrenergic receptor function in the urethra after parasympathetic decentralization (Koyanagi et al., 1988). Nordling et al. (1981) described a similar change in women after radical hysterectomy and ascribed this change to damage to the sympathetic innervation of the LUT.

When permanent LUT dysfunction occurs after radical pelvic surgery, the pattern is usually one of impaired bladder contractility or a failure of the bladder to voluntarily contract. Urodynamically, obstruction may be

seen from likely residual fixed striated sphincter tone, which is not subject to voluntarily induced relaxation. Often, the smooth sphincter is open and nonfunctional. Whether this appearance of the bladder neck and proximal urethra is caused by parasympathetic damage or terminal sympathetic damage or whether it results from the hydrodynamic effects of obstruction at the level of the striated sphincter is debated and unknown. **Decreased compliance is common in these patients, and, with the "obstruction" caused by fixed residual striated sphincter tone, may result in storage and emptying failure. These patients often experience leakage across the distal sphincter area and are unable to empty the bladder, because, although intravesical pressure may be increased, they cannot mount a true bladder contraction. The patient often has urinary incontinence that is characteristically and most commonly initiated with increases in intra-abdominal pressure.** This is usually most obvious in women, because the prostatic bulk in men often masks an equivalent deficit in urethral closure function. Alternatively, patients may have variable degrees of urinary retention.

Urodynamic studies may show decreased compliance, poor proximal urethral closure function, loss of voluntary control of the striated sphincter, and a positive bethanechol supersensitivity test, findings similar to those in Fig. 116.4. **Upper tract risk factors are related to intravesical pressure and the detrusor leak point pressure, and the therapeutic goal is always low-pressure storage with periodic emptying. In men, the temptation to perform a prostatectomy should be avoided unless a clear bladder outlet obstruction is demonstrated at this level.** Otherwise, prostatectomy simply decreases urethral sphincter function and thereby may result in the occurrence or worsening of sphincteric urinary incontinence.

We strongly urge caution in the early postoperative period, because the temptation to "do something" other than perform CIC initially after surgery in these patients is often strong, especially in those patients with little or no preexistent voiding dysfunction because most of these dysfunctions will be transient. Frequently, 6 to 12 months may elapse before detrusor function returns to an acceptable level (Blaivas and Chancellor, 1995b). Many of the changes after radical pelvic surgery are similar to those seen in sacral cord injury or disease. In an excellent study on decreased bladder compliance after decentralization, Sislow and Mayo (1990) noted a higher prevalence of this finding in patients who had undergone radical pelvic surgery than in those who had sustained conus medullaris or cauda equina injury.

Simple and Radical Hysterectomy

Questions remain as to whether nonradical pelvic surgery such as simple hysterectomy can be ultimately responsible for storage or emptying abnormalities on the basis of neurologic damage. In a multicenter Danish trial (Gimbel et al., 2005), a total of 319 women with benign disease were randomized to undergo either total abdominal hysterectomy (158) or subtotal abdominal hysterectomy (161). At 1-year follow-up after intervention, urinary incontinence was less often noted in patients undergoing total abdominal hysterectomy. Both groups, however, did experience an increase in incomplete emptying requiring double voiding. Both groups experienced an overall decrease in urinary incontinence frequency as compared with baseline. At this time, there is no consensus opinion, and more series that include sophisticated preoperative and early and late postoperative urodynamic evaluation are necessary.

In a study of the effects of hysterectomy on LUT function, 430 women who underwent either vaginal or abdominal hysterectomy for benign conditions (without prolapse as an indication) were assessed. Patients completed validated questionnaires before surgery and up to 10 years after surgery. Significant differences were noted between the vaginal and abdominal approaches in terms of symptoms as measured by the Urogenital Distress Inventory and Defecation Distress Inventory questionnaires. Women who underwent hysterectomy by the vaginal approach were more likely to have micturition symptoms as compared with abdominal approach patients (18% vs. 8%). In addition, defecation symptoms also appeared to be more common after vaginal hysterectomy (58% vs. 46%) (Lakeman et al., 2011; Sultan and Thakar, 2006). As compared with simple hysterectomy, radical hysterectomy may have more debilitating effects on bladder and bowel function. In a study of 209 patients undergoing radical hysterectomy for malignant disease with a survey return rate of 32% (66 of 209) (Brooks et al., 2009), 42% of patients undergoing radical hysterectomy reported mild incontinence symptoms as compared with 50% of controls. Moderate symptoms were seen in 34% of subjects and 35% of controls. Moderate-to-severe symptoms were noted in 18% of subjects and 14% of controls. Fecal symptoms did not differ between subjects and controls. Radical hysterectomy in this group did not appear to be associated with more long-term bladder or anorectal dysfunction (Brooks et al., 2009). In addition, nerve-sparing radical hysterectomy has been shown to result in reduced long-term urinary symptoms, while maintaining oncologic principles, in a randomized controlled trial of 92 women with cervical cancer (Roh et al., 2015).

Childbirth

There have been no prospective trials documenting a long-term follow-up relationship between urinary dysfunction and method of delivery, and no prospective clinical trials have been done to determine if cesarean section is protective against the development of incontinence. The debate regarding cesarean section as an alternative to spontaneous vaginal delivery and impact of each on the LUT also continues. The Epidemiology of Incontinence in the County of Nord-Trøndelag (EPINCONT) study assessed 15,307 women for the development of voiding dysfunction during longitudinal follow-up. The risk of urinary incontinence of all types was noted to be higher in women who had had cesarean sections as compared with nulliparous women and those who had had vaginal deliveries. However, the risk of moderate to severe incontinence was actually less in patients who had undergone cesarean sections than in those who had delivered vaginally. Urgency incontinence was the only exception, being equal across all groups. The adjusted ratio for any incontinence in women after cesarean section was 1.5 versus 1.7 for women with vaginal deliveries. Stress incontinence appeared to be associated with mode of delivery (Rortveit et al., 2003a, 2003b). McKinnie et al. (2005) studied 1004 women over an 18-month period to determine the relationship between urinary and fecal incontinence and type of delivery. In this study, pregnancy increased the overall risk of urinary and fecal incontinence, and there was no apparent relationship to mode of delivery.

Herpesvirus Infections

Invasion of the sacral dorsal root ganglia and posterior nerve roots with herpes zoster virus may produce urinary retention and detrusor areflexia days to weeks after the other primary viral manifestations (Ryttov et al., 1985). In general, painful cutaneous eruptions secondary to the virus are also present, but initially the patient may have only fever, malaise, perineal and thigh paresthesias, and obstipation. **Urinary incontinence secondary to detrusor overactivity may also occur, but the pathophysiology is unclear.** It may be related to nerve root irritation, inflammation of the meninges or spinal cord, or “zoster cystitis” (Broseta et al., 1993). Cystoscopy may reveal vesicles in the bladder mucosa similar to those seen on the skin. **Spontaneous resolution**

usually occurs in 1 to 2 months. Out of 57 patients with herpes zoster infection, 15 (26%) showed urologic manifestations, but only 2 had frank urinary retention (Broseta et al., 1993). Three patients demonstrated urinary incontinence, and all 3 demonstrated detrusor overactivity on urodynamics. Ten patients demonstrated irritative storage symptoms with dysuria and frequency.

Out of 423 patients admitted with a diagnosis of herpes zoster LUT, 17 (4%) had voiding dysfunction (Chen et al., 2002). Excluding those with cranial rather than spinal nerve involvement, the incidence was 8.8%; however, when only patients with lumbosacral dermatome distribution were considered, the figure rose to 28.6%. The authors subdivided the bladder disorders into three types. Twelve of the 17 affected patients (71%) had voiding dysfunction caused by herpetic cystitis and had dysuria, frequency, retention, pyuria, or hematuria on presentation. Four of the 17 patients (24%) had neuritis-associated voiding dysfunction, presumably affecting the sacral motor neurons, and on presentation had urinary retention with a “flaccid bladder.” One patient had myelitis-associated voiding dysfunction with spinal cord involvement, with detrusor overactivity on presentation. All 17 patients regained a normal or “balanced bladder” within 8 weeks, and no major urologic sequelae were noted.

Urinary retention has also been reported to occur in association with anogenital herpes simplex virus infection. Caplan et al. (1977) reported 11 such patients with the typical clinical picture of herpes genitalis, all of whom developed urinary retention 2 to 7 days after the genital eruption. Three such patients showed pleocytosis of the cerebrospinal fluid, a finding that Hemrika et al. (1986) believed was indicative of CNS involvement. They termed the coexistence of bilateral involvement of the sacral nerve roots of rapid onset accompanied by sphincteric incontinence with cerebrospinal fluid pleocytosis the ***Elsberg syndrome*** and tabulated 47 such cases reported before their article. Haanpaa and Paavonen (2004) added 2 patients, both of whom had transient urinary retention but developed chronic neuropathic pain in the sacral area. As with herpes zoster, the LUT dysfunction was transient.

Diabetes Mellitus

Diabetes is the most common cause of peripheral neuropathy in Europe and North America. The exact prevalence of diabetes in the United States is between 1% and 6%, depending on whether one includes only diagnosed patients and on the fasting blood glucose criteria used for inclusion (the higher estimate of prevalence represents a reduction in blood glucose criteria to 126 mg/dL) (Chancellor and Blaivas, 1995a; Goldman and Appell, 2000a). The clinical spectrum of LUT dysfunction thought to be caused by diabetes has been extensively reviewed by a number of authors (Beck et al., 1994; Chancellor and Blaivas, 1995a; Goldman and Appell, 2000a; Kaplan and Blaivas, 1988; Kaplan et al., 1995; Wein and Rovner, 1999). The exact incidence of LUT dysfunction caused by diabetes is uncertain; **however, 5% to 59% of patients with diabetes report symptoms of LUT dysfunction.** In attempting to estimate the true incidence and types of LUT dysfunction specifically associated with diabetes, clinicians must carefully discriminate between articles that consider patients referred for voiding symptoms versus those that have evaluated unselected patients from a population known to have diabetes. In the Nurses' Health Study, urinary incontinence was found to be more prevalent in women with diabetes (8.7% vs. 5.3% of controls). The odds of developing urinary incontinence increased by 20% with diabetes. The predominant type of associated incontinence noted in this study was urge incontinence. No association between diabetes and stress incontinence was recognized (Danforth et al., 2009).

Current evidence points to a sensory and a motor neuropathy as being involved in the pathogenesis, with the motor aspect contributing to the impaired detrusor contractility. **The classic urodynamic findings include impaired bladder sensation, increased cystometric bladder capacity, decreased bladder contractility, impaired uroflow, and, later, increased residual urine volume.** At least in men, the main differential diagnosis is bladder outlet obstruction, because both conditions commonly produce a low urinary flow rate; however, pressure-flow urodynamic studies easily differentiate the two. **Smooth or striated sphincter dyssynergia usually is not seen in classic diabetic cystopathy,** but these diagnoses can easily be erroneously made on a poor or incomplete urodynamic study (e.g., voiding may involve abdominal straining, which will produce an interference electromyographic pattern [pseudodyssynergia], and abdominal straining alone will not open the bladder neck area).

Other authors have suggested that findings seen in classic diabetic cystopathy may not represent the predominant form of LUT dysfunction. Chancellor and Blaivas (1995a) detailed the urodynamic findings in 43 patients with diabetes, with 33% having involuntary bladder contractions with normal contractility, 23% having involuntary bladder contractions with impaired contractility but were able to void, 9% having impaired bladder contractility alone but were able to void, 23% having detrusor areflexia, and only 12% having a normal urodynamic study. Ueda et al. (1997) also found involuntary bladder contractions in a moderate percentage of patients with diabetes (25%) but noted that all these patients had a history of cerebrovascular disease and that no patient had involuntary bladder contractions who did not have such a history. Although it is obvious that some (or even many) of the patients with diabetes who exhibited involuntary bladder contractions may have had factors other than diabetes to account for their bladder overactivity, the importance of urodynamic study in patients with diabetes before the institution of therapy cannot be overemphasized.

Alloxan-induced diabetic rats demonstrate detrusor overactivity, whereas sucrose-fed rats demonstrate normal bladder contractions. In addition, streptozotocin-induced diabetic rats more commonly demonstrate pyuria, raising the question of an inflammatory component. Therefore the type of model used should be considered when attempting to interpret experimental findings (Yoshimura et al., 2003). Liu and Daneshgari (2005) concluded that the bladders of diabetic and diuretic rats weighed more than control animals and that diabetes and diuresis caused a significant increase in overall fluid intake, urine output, and bladder size. An increased response after field stimulation was noted in diabetic and diuretic conditions, and a reduced response to cholinergic activity was noted as compared with controls. The authors noted that this finding indicated the possibility of neurogenically mediated bladder contraction in the diabetic rat. Numerous authors have proposed potential pathophysiologic mechanisms that could account for the various types of voiding dysfunction seen in diabetic patients. Clark and Lee (1995) describe the basic mechanism of interference with physiologic mechanisms as increases in blood glucose increasing the intercellular accumulation of glucose and its subsequent metabolic products. Hyperglycemia is then proposed to lead to microvascular and neurologic complications, with the neurologic sequelae ultimately resulting in a loss of myelinated and unmyelinated fibers, wallerian degeneration, and blunted nerve fiber reproduction and function. The proposed mechanisms include increased accumulation of polyols (sorbitol) from glucose through the aldolase-reductase pathway, inhibiting glomerular and neural synthesis of myo-inositol. The decrease in myo-inositol synthesis depresses phosphoinositide metabolism, decreasing Na^+,K^+-ATPase activity. Hyperglycemia also leads to the formation of advanced glycosylation end products, inhibition of the formation of which in animals has been shown to improve response to functional and structural abnormalities of peripheral nerves. In a study of 47 patients with type 2 diabetes and LUTS, increased serum measurements of glycosylation end products correlated with impaired detrusor function (Gali et al., 2017).

NGFs and other nerve trophic factors also appear to play a role in regulation of the pathogenesis of diabetic voiding dysfunction. In addition, nitrergic and adrenergic mechanisms also contribute to the ultimate pathophysiologic cascade of this condition (Torimoto et al., 2009). In another report of streptozotocin-induced diabetic rats, the diabetic condition was associated with increased bladder weight. This was associated with a decreased blood vessel density that occurred on a time-dependent basis. In a comparator group of polyuric animals, similar changes were noted. These findings appeared to support not only direct change but also diuretic-induced changes as being an additional physiologic consequence of the diabetic condition (Liu et al., 2011).

Another aspect of diabetic bladder dysfunction may occur at the organelle level. In rodent models, morphologic changes in chronic diabetes have also included mitochondrial abnormalities, particularly in the urothelium. Increased collagen was noted to be deposited in capillary walls, with an interruption or extensive widening of the gap junctions between myocytes in the bladder muscularis. Reduced mitochondrial counts were noted in the urothelium and bladder muscle. Degenerated nerve fibers and myelin bodies were identified between myocytes, with increased collagen and mast cell inflammatory aggregates noted in the stroma of diabetic rats as compared with nondiabetic controls. The duration of diabetes appeared to amplify these changes, and the authors concluded that diabetic changes were a time-dependent phenomenon (Rizk et al., 2006).

In addition to this overall hypothesis, there are interesting data from various investigators that may or may not prove to be involved in the pathogenesis of diabetic voiding dysfunction. In streptozotocin-induced diabetic rats, Hashitani and Suzuki (1996) reported reduced spontaneous spike activity, failure of neuromuscular transmission, reduced potency of the smooth muscle sodium-potassium pump, and the development of a post-junctional, muscarinic supersensitivity, without alteration of the ATP receptor sensitivity. Mumtaz et al. (1999) reported an impairment of nitric oxide–mediated urethral smooth muscle relaxation in alloxan-induced diabetic rabbits along with a significant impairment of nonadrenergic, noncholinergic (NANC) nerve-mediated relaxation in this area. They hypothesized that nitric oxide may be functionally inactive and/or unavailable in this type of diabetes, and this lack may contribute to non–benign prostatic hyperplasia (BPH)–related outlet obstruction in patients with long-term diabetes and to detrusor overactivity, although it is a bit unclear how changes in only the outlet may influence overactivity. In addition to the inhibitory nitric oxide, the NANC pathway is mediated by purinergic receptors (e.g., P2X), which can induce bladder contractions. In streptozotocin-induced diabetic rats, muscarinic and purinergic receptors had increased expression, which was associated with increased bladder contractility compared with controls (Yoshizawa et al., 2018). Gupta et al. (1996) and Gupta and Wein (1999) suggested that diabetes diminishes sodium pump activity, thereby inhibiting agonist-induced contractions in bladder smooth muscle by an increase in intracellular sodium concentration, the latter acting to diminish calcium influx. Cardozo et al. (2002) reported enhancement of bladder contractions to substance P and des-Arg-bradykinin in a streptozotocin model. Sasaki et al. (2002) described decreased NGF in bladder tissue and L6 to S1 dorsal root ganglia. In alloxan-induced diabetic animals, Khan et al. (2002) noted decreased apoptosis of bladder urothelial cells. In this same model, Su et al. (2004) reported increased myosin light chain phosphorylation and decreased sensitivity to activator calcium. Changolkar et al. (2005) reported decreased smooth muscle force associated with increased lipid peroxides and sorbitol and an overexpression of aldolase reductase and polyol pathway activation. Another interesting pathophysiologic explanation is one that is attributed to autoimmune phenomena. Antibody-mediated bladder dysfunction in type 1 diabetes has been identified in a murine model, in which anti–voltage-gated calcium channel antibodies induce urodynamic findings such as phasic detrusor contractions and also loss of bladder wall compliance compatible with overactive bladder. The autoimmune dysfunction was reversed by the administration of agonists for voltage-gated calcium channels. The possible reversibility of this phenomenon remains intriguing for early stage treatment (Wan et al., 2007).

Hyperglycemia-induced oxidative stress in detrusor smooth muscle resulting in microvascular and macrovascular events has been postulated to contribute to urologic symptoms and complications associated with diabetes (Kirschner-Hermanns et al., 2012). In addition, further evidence of oxidative stress has been identified by comparative gene expression studies. When nondiabetic versus streptozotocin-induced–diabetic animals were assessed for oxidative stress via a variety of protein-based metabolic assays (glutathione and *S*-transferase activity, lipid peroxidation, and carbonylation and nitrosylation of proteins), global gene expression in the diabetic animals demonstrated a significant increase in markers for oxidative stress. This was subsequently further hypothesized to have a downstream effect on protein damage and apoptosis. This hypothesis was confirmed by demonstrating an increase in protein degradation products (Nedd-4 and LC3B) in diabetic bladders. The conclusion was that oxidative stress resulted in aberration and protein-based pathways resulting directly from oxidative stress (Kanika et al., 2011).

Tong et al. (1999) reported an upregulation of M_2 receptor protein in the bladder of streptozotocin-induced diabetic rats and an upregulation of M_2 receptor protein in bladder body tissue (Tong and Cheng, 2002). Presumably, this could be related to detrusor overactivity and conceivably account for a differential effect of various anticholinergic agents, depending on their receptor specificity. In a trial using rodent (mouse) exposure to streptozocin in an M_2 muscarinic receptor knockout model as compared with wild-type specimens, the M_2 receptor was found to modulate bladder overdistention associated with streptozocin-induced neuropathy and therefore preserve function. The difference between function in the wild-type versus the knockout model approximated a 70% difference in those animals with retained M_2 receptors (Pak et al., 2010a). With the same study construct (wild type versus M_2 muscarinic receptor knockout exposure to streptozotocin), rodents were exposed to oxotremorine-M (an M_2 muscarinic agonist). In the wild-type animals, contractile function was maintained by enhanced mediation by M_2 contractile activity despite loss of M_3 activity in these animals (Pak et al., 2010b).

Smooth-muscle ultrastructural and functional changes in detrusor smooth muscle associated with streptozotocin-induced bladder dysfunction in mice has been attributed to the contribution of the L-type voltage-operated channels (L-VOCCs). The presence of these receptors and an increased density of M_3 receptors were noted in streptozotocin-induced diabetic animals. The role of these L-VOCC channels continues to be explored (Leiria et al., 2011). Another channel, TRPV1, expressed in bladder afferent nerves has also been implicated in the bladder dysfunction associated with diabetes (Sharopov et al., 2018).

Therefore the pathophysiology of diabetic cystopathy can be attributed to five possible sources (Nanigian et al., 2007)**:**

1. **Alterations in muscarinic receptor densities specifically with overexpression of M_2 receptors may be one mode of dysfunction.**

2. **Direct neural damage caused by hyperglycemia resulting in glycosylated end products may accelerate microvascular disease as well as inducing endothelial dysfunction and causing a deleterious effect on nitric oxide release.**
3. **In addition, the production of sorbitol in a hyperglycemic environment may increase reactive oxygen species, resulting in oxidative stress at the muscle cell level.**
4. **Hyperglycemia may, as well, increase the production of diacylglycerol, resulting in the activation of protein kinase C, which affects transcription of a variety of connective tissue constituents including type IV collagen, contractile proteins, and fibronectin, as well as damaging local endothelial and neural cells.**
5. **Finally, there may be a decrease in NGF, which has been previously hypothesized to protect bladder activity.**

Early institution of timed voiding will avoid some of the impaired detrusor contractility from chronic distention and detrusor decompensation. Experimental studies are currently directed at inhibiting the proposed mechanisms by which hyperglycemia produces neuropathy (Clark and Lee, 1995). Ayan et al. (1999) cite references showing that intensive therapy for diabetes can slow its progression and slow the development of abnormal autonomic tests. On a short-term basis, the authors showed that insulin therapy in alloxan-induced diabetic rabbits prevented the urodynamic effects (e.g., increased bladder capacity and compliance) and histopathologic changes seen in a similar but non–insulin-treated group of animals. Insulin reversed most of the changes reported by Cardozo et al. (2002). Despite improvement in other organ systems with enhanced glycemic control, LUTS in patients with type 1 diabetes do not appear to respond well to otherwise well-documented glycemic control (Van Den Eeden et al., 2009).

A prospective evaluation of women with type 2 diabetes assessed urodynamic findings as compared with responses to Aδ and C fibers in the bladder using intravesical current responses to threshold frequencies at 250 and 5 Hz, respectively. Of the 86 women evaluated, 34.9% had detrusor underactivity, 14% (12) had detrusor overactivity, 12.8% (11) had bladder outlet obstruction by the criteria of the trial, and 38.4% (33) had normal detrusor function. With the normal detrusor function group used as a comparator, the underactivity group showed not only decreased emptying capabilities but also decreased sensation on cystometry and intravesical current perception threshold testing. The overactivity group demonstrated impaired storage and emptying function but had no significant changes in intravesical current reception. In this trial, an increase in current perception threshold values was associated with a decrease in bladder voiding efficiency at 5 and 250 Hz. These data underscored the evidence that impaired Aδ, as well as C-fiber function, had direct effect on bladder pathways for emptying in patients with diabetes mellitus (Lee et al., 2009). Pop-Busui et al. (2015) studied 635 men with type 1 diabetes and found an association between autonomic neuropathy and LUTS, suggesting a clinical association between diabetes and bladder dysfunction as a result of autonomic neuropathy. The **exact mechanism for diabetic cystopathy has not been precisely elucidated and is likely a result of multifactorial insults on the neurologic and cardiovascular systems and the bladder**.

Key Point: Diabetes

- Detrusor overactivity has been cited as the most frequent urodynamic finding in diabetic cystopathy. This could be a result of a difference in the time of diagnosis with reference to the natural history of the effects of diabetes on the LUT.

Guillain-Barré Syndrome

Guillain-Barré syndrome (GBS) is **a potentially life-threatening, inflammatory demyelinating disorder of the peripheral somatic and autonomic nervous system.** It is described as a recognizable clinical entity characterized by rapidly evolving symmetrical limb weakness, loss of tendon reflexes, absent or mild sensory signs, and variable autonomic dysfunctions (Hahn, 1998). It results from aberrant immune responses directed against peripheral nerve components (Hahn, 1998; Hartung et al., 1995) and is triggered by a preceding bacterial or viral infection, with the immune responses directed toward the infecting organisms cross-reacting with neural tissues. The immune reactions against Schwann cell surface membrane or myelin result in acute inflammatory demyelinating neuropathy (accounting for 85% of cases), whereas reactions against axonal membrane components cause acute motor-sensory axonal neuropathy, accounting for the remaining 15%. Two-thirds of patients report an antecedent acute infectious illness, most commonly respiratory tract infection or gastroenteritis that has resolved by the time the neurologic symptoms begin. Several anecdotal case reports have linked GBS to vaccination by temporal association alone. About 75% of cases reach their nadir within 2 weeks, and 94% within 4 weeks. After a brief plateau phase, paralysis gradually resolves over weeks to months. In general, the outcome is favorable, but Hahn (1998) quotes a mortality rate of 5% to 8% despite the most aggressive management. **Autonomic neuropathy is a common complication.** Cardiac arrhythmia, hypertension and hypotension, and bowel, bladder, and sexual dysfunction may occur. **The prevalence of LUT dysfunction ranges from 25% to more than 80%** (Wyndaele et al., 2005). Zochodne (1994) reviewed multiple series and reported a urinary retention rate of 11% to 30%. Of the 7 of 28 GBS patients with voiding dysfunction, 3 had transient urinary retention; 2 had urgency, nocturia, and urge incontinence; 1 had stress incontinence; and 1 had otherwise unexplained voiding difficulty (Sakakibara et al., 1997a, 2009). Although many of these patients may have an indwelling catheter in the acute setting, **their voiding dysfunction should be managed by reversible therapy** (e.g., CIC, anticholinergic therapy) pending resolution. The urinary symptoms associated with GBS are multifaceted. In other reports, approximately 27% of patients with GBS have demonstrated urinary symptoms, with urinary retention being present in 9.2% of patients. Defecatory dysfunction and urinary dysfunction are highly related to the motor grade of GBS symptomatology. Antibody titers have no relationship to symptomatic urinary dysfunction. The most common urinary findings include increased postvoid residual volume, followed by decreased bladder sensation, detrusor overactivity, diminished bladder compliance, and underactive detrusor contraction, as well as sphincteric dyssynergia. These findings underscore the difficulty in prediction of LUTS based on condition diagnosis only (Sakakibara et al., 2009). In another study of GBS patients, 38 patients were assessed using Hughes motor grading, overall disability sum score (ODSS), and Medical Research Council (MRC) sum score with urodynamics at baseline and at 2 months. Ten of 38 patients had urinary symptoms; 23 of the 38 had urodynamic abnormalities; the most significant was detrusor underactivity in 15 patients. DSD was found in 6 patients, bladder acontractility in 5, and detrusor overactivity in 3. There was a correlation between disability based on these scoring systems and urodynamic findings (Naphade et al., 2012).

Miscellaneous Neurologic Diseases Causing Lower Urinary Tract Dysfunction

Amyotrophic Lateral Sclerosis

Amyotrophic lateral sclerosis (ALS), also known as Lou Gehrig disease, is a fatal neurodegenerative disorder of upper and lower motor neurons. There is no known cure for ALS and treatment is supportive. Symptoms include muscle weakness, cramping, and, in later stages, dysphagia, dyspnea, and eventually respiratory failure. There have been few studies on the effect of ALS on the lower urinary tract, but in a recent descriptive study by Arlandis et al. (2017), of 55 patients with ALS, 24 (43.6%) had clinically significant LUTS based on questionnaires. Of those patients reporting LUTS, the majority had storage and voiding symptoms and 26% reported urge incontinence. Urodynamic evaluation was done on 10 of these patients of which 7 had detrusor overactivity with a nonrelaxing external sphincter (5 patients) or bladder neck (2 patients). Although LUTS are not commonly associated with ALS, there is a high prevalence in this population, and treatment may be indicated to maintain quality of life.

Lyme Disease

The associated neurologic symptoms of Lyme disease (neuroborreliosis) fall broadly into three syndromes: (1) encephalopathy, (2) polyneuropathy, and (3) leukoencephalitis. The Lyme spirochete can also (rarely) invade the bladder. Puri et al. (2013) compared LUT symptoms in 17 patients with Lyme disease with matched controls and found that 35% of patients with Lyme disease had symptoms of bladder dysfunction, whereas none of the controls reported symptoms. Chancellor et al. (1993) described seven patients who also had LUT dysfunction. Five had detrusor overactivity, none had dyssynergia, and two had detrusor areflexia. In two women, urinary retention was the presenting symptom of Lyme disease. Other subjective symptoms noted were urgency, frequency, nocturia, and urge incontinence. Follow-up at 6 months to 2 years after treatment revealed residual urgency and frequency in three patients.

Hereditary Spastic Paraplegia

Hereditary spastic paraplegia (HSP) is a genetically transmitted disorder, usually autosomal dominant, less commonly autosomal recessive, and rarely sex linked. There is a pattern of central demyelination with axon loss and progressive lower extremity spasticity with muscle weakness. Bushman et al. (1993) described three patients, two of whom had detrusor overactivity (one with striated sphincter dyssynergia), one who had significantly decreased compliance, and one who was urodynamically normal except for a high maximum urethral pressure of uncertain significance. Pure forms of this disease are associated with primary lower extremity spasticity at presentation, but variance exists.

Jensen et al. (1998) reported the voiding characteristics of 11 patients with autosomal dominant pure spastic paraplegia linked to chromosome 2p21-p24. These patients were culled from 6 of 8 families with the disorder; the authors commented that LUTS were present in 16 of 44 definitely affected family members. One patient had an indwelling catheter, and thus an accurate description of symptomatology was not possible. For the other patients, urinary urgency and frequency were the dominant complaints, with 6 of these 10 patients regularly experiencing urgency urinary incontinence. Urodynamically, 3 patients showed detrusor overactivity, 6 demonstrated normal detrusor activity, and 1 demonstrated “hyporeflexia” with delayed first sensation. Satisfactory sphincter electromyographic recordings were obtained from 7 patients, and all were normal. Postvoid residual urine volumes were elevated in 8 of 10 patients. The bulbocavernosus reflex was absent in 6 patients and was truly normal in only 1 patient. The authors commented that the frequency of urinary symptoms in their patients (36%) correlated well with other reports in the literature. They proposed that the LUTS (along with bowel and sexual dysfunction) in patients with this disorder are caused by a combination of somatic and autonomic nervous system involvement, supporting a multisystem involvement. LUT dysfunction is well recognized in this condition and is associated with high prevalence rates in those of Eastern European extraction (approaching 77%). In a study of 29 HSP patients, the primary urinary symptom was urgency in 72%, followed by frequency in 65%, incontinence in 55%, and hesitancy in 51%. Urodynamic findings included detrusor overactivity in 51% and sphincter dyssynergia in 66%, with increased postvoid residual volume in 41%. However, there was no significant risk of upper tract complications related to this condition (Fourtassi et al., 2012). In another study of patients with HSP, 49 patients were assessed and 38 (77.6%) had some urinary concern. LUT dysfunction occurred similarly in the pure and complex forms of the disease. The most common symptoms associated with this condition were urinary incontinence of any type (69.4%), urinary hesitancy (59.2%), increased frequency (55.1%), and associated urinary urgency (51.0%). Incomplete bladder emptying was the least common (36.7% of patients). Increased LUT dysfunction was more commonly associated with the female gender (Braschinsky et al., 2010).

Tropical Spastic Paraparesis

Tropical spastic paraparesis is primarily a spinal cord myelopathy caused by a retrovirus (human T-cell leukemia virus 1 [HTLV-1]) that is similar to human immunodeficiency virus (HIV). Progressive lower limb weakness and back pain are typically the primary complaints, but LUT dysfunction occurs in up to 60% of those affected (Walton and Kaplan, 1993). Troisgros et al. (2017) reviewed 60 patients with HTLV-1–associated myelopathy who underwent urodynamic evaluation. The most common urodynamic abnormalities were DSD in 78% and detrusor overactivity in 68.3%. Bladder compliance was decreased in 25%, and 21.7% had detrusor underactivity. Walton and Kaplan (1993) found that 4 of 5 consecutive patients had detrusor overactivity and DSD, whereas 1 had overactivity and synergia. The type of voiding dysfunction depends on whether the damage is primarily to the descending spinal tracts, to the sacral nuclei, or to the sacral outflow. The disease must be distinguished from other myelopathic conditions associated with LUT dysfunction, such as multiple sclerosis.

Acquired Immunodeficiency Syndrome

Infection with HIV can affect the central and the peripheral nervous systems, and so it is not unexpected that symptoms of LUT dysfunction occur. As with many other conditions, there is some disagreement as to the overall prevalence of such symptoms in this population. AIDS-related neurogenic voiding dysfunction is associated with a poor outcome, with a mortality rate of approximately 40% within 8 months of development of urologic symptoms (Heyns and Fisher, 2005). In a prospective study of 39 patients with HIV infection and voiding symptoms, clinical symptoms included frequency, urgency, and incontinence in 41% of patients, acute urinary retention in 28%, dysuria and frequency in 18%, and decreased flow in 13% (Hermieu et al., 1996). Seventeen of the patients had involuntary bladder contractions, and, of these, 8 had DSD or a lack of sphincter relaxation during micturition, 5 had detrusor areflexia, 4 had what was termed a “hypertonic urethra,” 3 had “hypersensitivity,” and 5 had a normal urodynamic evaluation. The authors characterized the voiding dysfunctions broadly as inability to void in 41% of the cases and frequency, urgency, or incontinence in 41%. Furthermore, the authors proposed that the appearance of neurogenic voiding disturbances heralded a poor prognosis. Eighteen HIV-positive patients, 13 with acquired immunodeficiency syndrome (AIDS), with voiding dysfunction were urodynamically characterized by Kane et al. (1996). Chief presenting complaints were daytime frequency in 8 patients, retention in 3, nocturia in 2, and having to strain to void, feeling incompletely empty, and having incontinence, a split stream, or groin pain in 1 each. Five patients (28%) showed detrusor overactivity, 5 showed DSD, and 1 (6%) showed detrusor areflexia. The authors remarked that there is a correlation among cytomegalovirus infection, polyradiculopathy, and detrusor areflexia, which is a phenomenon reported by others as well. Lima et al. (2002) evaluated a group of 26 men with HIV-induced bladder dysfunction. Eighty percent of those patients demonstrated detrusor overactivity, and 34% had detrusor-sphincter dyssynergia. These findings are indicative of the myopathy associated with HIV (Lima et al., 2002). Other common causes of LUT dysfunction exist as well: 5 patients had outlet obstruction, 4 secondary to BPO and 1 from urethral stricture. The fact that HIV can cause demyelination at any site in the nervous system complicates symptom-based management of the HIV-infected patient and mandates sufficient LUT evaluation as a guide for therapy (Delgado et al., 2014). Renal functional impairment may result from LUT dysfunction or from primary renal involvement by the disease (Tonolini et al., 2013). Gyrtrup et al. (1995) prospectively investigated voiding function in 77 men and 4 women with HIV infection or AIDS consecutively attending an outpatient clinic. Eight of these (10%) had moderate subjective voiding problems, whereas two (2%) had severe problems. The authors believed that in only 4% of patients did the nature of the disturbance warrant urodynamic examination and concluded that urinary voiding symptoms are only a modest problem overall in an HIV/AIDS population. They concluded that neuropathic bladder dysfunction is rare and occurs mostly in the late stages of the disease. However, as treatment for HIV/AIDS improves, the mean age of patients will increase and along with that the incidence of more common LUT conditions, such as BPH. Consideration must be given to evaluate for possible neurogenic voiding dysfunction given the poor prognosis in this population, but treatment of benign causes for LUTS should not be overlooked.

Acute Disseminated Encephalomyelitis

Acute disseminated encephalomyelitis (ADEM) is an acute inflammatory demyelinating disorder of the CNS of unknown cause. It is also sometimes known as *parainfectious* or *postinfectious encephalomyelitis.* The locations of lesions are multifocal and can include the cerebral white matter, cerebellum, brainstem, and spinal cord. Of 61 patients with ADEM, 33% ($n = 20$) had LUTS with retention being the most common in 16, followed by incontinence in 4, urgency in 3, and frequency in 2. On urodynamic evaluation, detrusor overactivity was present in 4 and detrusor underactivity in 4 (Panicker et al., 2009). Three months after treatment, 5 patients had persistent symptoms. In another study of 11 patients with ADEM, 9 had urinary retention; the other 2 had urgency, frequency, nocturia, and difficulty voiding (Sakakibara et al., 1996b). One patient in the latter group had enuresis and urgency incontinence as well. The urodynamic findings are difficult to correlate with the presenting symptoms, because in 4 of the patients the studies were done considerably after the onset of the disease. During the follow-up period, 7 of the 9 patients who originally had retention became able to urinate. Five had difficulty voiding, and four developed irritative symptoms. Six of the patients ultimately had a near-complete neurologic recovery, but voiding symptoms persisted in 3. The authors concluded that the supra-nuclear and nuclear types of pelvic and pudendal nerve dysfunction were primarily responsible for the micturitional disturbances in patients with this disease and that voiding dysfunction was very common in these patients.

Syringomyelia

Syringomyelia is a chronic disorder of the spinal cord characterized by dissociated sensory loss and brachial amyotrophy. It usually affects the cervical spinal cord but can extend caudally. LUT dysfunction has been reported in 9% to 25% of patients. Fourteen patients with syringomyelia were studied urologically by Sakakibara et al. (1996c). Eleven of these had urinary symptoms: difficulty voiding in 8, retention in 3, nocturnal and daytime frequency in 3, incontinence in 2, and urgency and enuresis in 1. The urinary symptoms appeared from 2 months to 13 years after the initial neurologic symptoms. Urodynamic studies revealed detrusor overactivity in 7, DSD in 4, detrusor areflexia in 4, and “uninhibited sphincter relaxation” in 2. Motor unit electromyographic recordings disclosed findings compatible with denervation of the striated sphincter in 5 of 6 patients. The authors concluded that supranuclear and nuclear types of peripheral autonomic and somatic nerve dysfunction are responsible for the LUT dysfunctions seen. The micturitional status gradually improved in 4 of 6 patients after syringosubarachnoid shunts.

Schistosomal Myelopathy

Schistosomiasis is a tropical, parasitic disease and may cause LUT dysfunction from bladder neck obstruction and impaired muscle contractility as a result of infiltration of the bladder smooth muscle. In addition, it can rarely cause spinal cord involvement, either as a granulomatous intrathecal mass or as an acute transverse myelitis (Razdan et al., 1997). Two such patients had urinary incontinence as their chief urologic complaint, and both had detrusor overactivity, one without dyssynergia and with minimal motor weakness and one with DSD and a T11 sensory level. It was believed that the findings in the former patient were characteristic of a partial spinal cord or cerebral lesion and that the second patient had a suprasacral transverse myelopathy. In the first patient, the urinary symptoms developed approximately 2 months after exposure and after the development of systemic symptoms, whereas in the second case, symptoms developed some 5 years after the initial diagnosis.

Gomes et al. (2002) reviewed the records of 14 patients with schistosomal myelopathy referred because of LUT dysfunction. Of 5 patients with acute disease, 3 had retention and 2 were incontinent. Urodynamics were performed in three of these. Two (1 in retention, 1 with hesitancy and incontinence) demonstrated detrusor areflexia, and one (with retention) showed detrusor overactivity and DSD. Of the 9 patients with chronic disease, 5 showed detrusor overactivity with DSD, 1 had decreased compliance, 2 had overactivity with synergic sphincters, and 1 had detrusor areflexia with decreased compliance. In another study of 26 patients with schistosomiasis, all patients had chronic neurologic and urologic symptoms secondary to this diagnosis. The most common urinary symptoms were difficulty in bladder emptying in 65% of the patients followed by incontinence in 54% and urgency and frequency in 50% of the patients, UTI in 30% of patients, and bilateral hydronephrosis in 19%. Detrusor overactivity associated with sphincter dyssynergia was present in 54% of the patients; detrusor areflexia was present in 23% of the patients. Patients with dyssynergia had a much higher incidence of upper tract decompensation.

These findings are consistent with classically defined involvement of spinal cord as a common complication of this disease (Gomes et al., 2005).

Systemic Lupus Erythematosus

Systemic lupus erythematosus (SLE) is a disease with a likely autoimmune origin in which there is widespread inflammatory change in the connective tissues and small vessels of the skin and systemic organs (Hahn cited by Sakakibara et al., 2003b). The prevalence of nervous system involvement ranges from 18% to 75%, and myelopathy occurs in 1% to 3% of SLE patients. Sakakibara et al. (2003b) reported on eight patients with SLE with LUT dysfunction, six with voiding difficulty (two of whom had retention), and four with urinary incontinence. Five exhibited decreased flow, three had increased residual urine, five had detrusor overactivity, five had impaired detrusor contractility, four had DSD, and two of four patients studied exhibited abnormal striated sphincter electromyographic potentials. Sensation was impaired in two. Although three patients had subacute encephalomyelopathy (one subacute myelopathy, four chronic myelopathy), the LUT dysfunction seemed to have been related mainly to the myelopathy.

In addition, there have been reports of lupus cystitis affecting about 2% of patients with SLE (Koh et al., 2015). Lupus cystitis is characterized by bladder wall thickening and diffuse inflammation of the bladder mucosa with associated erythema and hematuria. Patients may also have bilateral hydronephrosis and/or vesicoureteral reflux. Treatment of the underlying disease process with steroids and immunosuppressive agents improves bladder findings (Harris et al., 2015).

Reflex Sympathetic Dystrophy

Reflex sympathetic dystrophy (RSD) is a disabling syndrome characterized by severe pain with autonomic changes, such as vasomotor disturbances. The condition usually follows a traumatic injury, although the exact cause and pathogenesis are unclear. The prevalence of LUT dysfunction in patients with RSD is unknown, but it must be more than a rare occurrence because Chancellor et al. (1996) were able to collect 20 consecutive patients with neurologically verified RSD who were referred because of new-onset voiding symptoms. Seven of the patients had urinary retention, although some of these had undergone various types of surgery designed to treat the symptoms of the dystrophy. Five presented with urgency incontinence, 1 of whom also had stress incontinence. Six had urgency as a primary complaint, 1 had daytime frequency, and 1 had severe nocturia. Detrusor overactivity was demonstrated in 8 patients, DSD in 1, detrusor areflexia in 8, and hypersensitivity on filling in 3. Because the authors excluded patients who acutely developed voiding dysfunctions after back surgery and those with herniated disks, one must conclude that significant LUT dysfunction can develop as a direct result of, or in association with, RSD. However, the cause-and-effect relationship is so far unclear.

Tuberculosis

Spinal tuberculosis has been associated with significant evidence of micturition disturbances including high postvoid residual volume and urinary symptoms. In an assessment of patients undergoing clinical urodynamics and spinal MRI, 30 spinal tuberculosis patients were assessed; 15 had some form of micturition disturbance, including urinary incontinence or storage disorder. Four of the 15 also demonstrated retention, 2 had stress incontinence, 6 had urinary hesitancy, 11 reported urgency, and 9 had urge incontinence. These symptoms were associated with a significant incidence of either paraparesis or quadriparesis (13 patients). Detrusor overactivity with high-pressure voiding was present in 6. Detrusor areflexia was present in 4, with the remainder having increased postvoid residual volumes. After intervention, those patients with prior micturition disturbances had poor functional recovery as compared with patients without micturition disturbances. There was a strong relationship between bladder symptomatology and severity of paraplegia, horizontal sensory level, and signal abnormality in the cord; these variables were associated with poorer outcome than in those patients without them (Kalita et al., 2010).

In a prospective study of 51 patients with tuberculous meningitis, 17 (33%) had urinary symptoms related to storage or voiding dysfunction, but 36 had an abnormal urodynamic evaluation. Reduced bladder sensations were present in 11 (31%) and NDO in 10 (28%). Three patients (8%) had detrusor areflexia and 6 (17%) had DSD. At 6 months after treatment, of the 36 patients with an abnormal UDS, 18 had resolution of the abnormalities (Gupta et al., 2013). Bladder dysfunction is common in patients with spinal tuberculosis but resolves in a large number of patients after treatment.

Miscellaneous Conditions Definitely, Probably, or Possibly Related to Neuromuscular Dysfunction

Detrusor Sphincter Dyssynergia

Dyssynergia* is the kinesiologic disassociation of two groups of muscles that, in general, work in harmony.** ***Sphincter dyssynergia is an involuntary contraction, or lack of relaxation, of either the striated sphincter (the striated muscle surrounding the proximal urethra and the striated muscle that forms a part of the urethra for a variable distance from the "urogenital diaphragm" to the bladder neck) or the smooth sphincter (the smooth muscle of the bladder neck and proximal urethra). ***Detrusor sphincter dyssynergia,*** unless specified otherwise, is dyssynergia of the striated sphincter and is sometimes abbreviated DSD or DESD.

True DSD should exist only in patients who have an abnormality in pathways between the sacral spinal cord and the brainstem PMC and is usually caused by neurologic injury or disease (Blaivas, 1982; Chancellor and Rivas, 1995; Rudy, 1993; Wein and Rovner, 1999). The diagnosis of DSD should be suspected in any patient with a neurologic lesion in this area. Common causes include traumatic SCI, MS, and transverse myelitis. Conversely, **in patients without such a lesion, this diagnosis should always be viewed with skepticism,** and, without such apparent pathology, such a patient deserves exhaustive study to exclude a neural diagnosis. One exception to this precept is in infants and children with dysfunctional voiding or the Hinman syndrome (see later).

Blaivas et al. (1981) have described three categories of DSD. In type 1 there is a concomitant increase in detrusor pressure and electromyographic activity; at the peak of the detrusor contraction, the sphincter suddenly relaxes and unobstructed voiding occurs. In type 2 there are sporadic contractions of the striated sphincter throughout the detrusor contraction. In type 3 there is a crescendo-decrescendo pattern of sphincter contraction that results in outlet obstruction throughout the entire detrusor contraction. Schurch et al. (2005) have correlated neurologic status and DSD type after SCI and found that those with an incomplete sensory and motor lesion typically have type 1 DSD, whereas those patients with complete sensory and motor lesions have type 2 and type 3. Weld et al. (2000) prefer to classify DSD as intermittent or continuous; however, in their experience the clinical significance of DSD type is not crucial because both types require urodynamic surveillance and expedient treatment to minimize complications. No significant association between type and level of injury was found; however, continuous DSD was more associated with complete injuries.

Sphincter electromyographic activity that increases simultaneously with intravesical or detrusor pressure does not always indicate true DSD. These instances are referred to as *pseudodyssynergia* (Wein and Barrett, 1982), and such a misdiagnosis may be accompanied by adverse therapeutic consequences. **Common causes of pseudodyssynergia include (1) abdominal straining to either initiate or augment a bladder contraction or in response to discomfort and (2) attempted inhibition of a bladder contraction either because of its involuntary nature or because of discomfort.** Rudy (1993) reported that pseudodyssynergia can reliably be differentiated from true DSD urodynamically by analyzing the patterns of detrusor and electromyographic activity, but others have not consistently found this to be the case.

Without proper treatment, more than 50% of men with DSD will develop significant complications, such as VUR, upper tract deterioration, urolithiasis, urosepsis, and ureterovesical obstruction (Chancellor and Rivas, 1995). In women, these complications are much less common, most likely a result of the lower detrusor pressures generated. Using Blaivas's categorization, type 1 DSD is usually managed with observation alone unless there is persistent VUR, hydronephrosis, or autonomic hyperreflexia, whereas types 2 and 3, in general, require treatment. In assessing success or failure of treatment, Kim et al. (1998) used bladder leak point pressure greater than 40 cm H_2O as an indicator of the failure of sphincterotomy, because in their experience there was a significantly higher incidence of upper tract damage and persistent DSD in such patients. This most likely applies to other treatments as well.

Therapy for DSD is designed to either eliminate or significantly minimize the abnormal sphincter activity or to bypass the sphincter. Oral medical therapy directed toward the striated sphincter has not enjoyed wide success. The most common treatment approaches currently are (1) CIC (usually combined with therapy to control detrusor overactivity), (2) sphincterotomy, (3) injection of onabotulinumtoxinA into the sphincter, (4) continuous indwelling catheterization, and (5) urinary diversion. Urethral stent placement across the sphincter has fallen out of favor because of complications (Wilson et al., 2002), and the device is no longer commercially available.

Dysfunctional Voiding

Dysfunctional voiding, also described by various authors as non-neurogenic neurogenic bladder, occult voiding dysfunction, occult neuropathic bladder, learned voiding dysfunction, and Hinman syndrome, demonstrates what urodynamically appears to be involuntary obstruction at the striated sphincter level existing in the absence of demonstrable neurologic disease (Hinman, 1986). It is very difficult to prove urodynamically that an individual has this entity, and the diagnoses in many of the patients reported have been made on the basis of only history, isolated flowmetry, isolated measurements of total intra-vesical pressure, and pelvic floor electromyographic activity (Wein and Barrett, 1988). Unequivocal demonstration of this entity requires pressure-flow electromyographic evidence of bladder emptying occurring simultaneously with involuntary striated sphincter contraction in the absence of any element of abdominal straining, either in an attempt to augment bladder contraction or as a response to discomfort during urination. Such reports do exist and confirm the existence of this syndrome. The cause is uncertain and may represent a persistent transitional phase in the development of micturitional control or persistence of a reaction phase to the stimulus of LUT discomfort during voiding, long after the initial cause of the problem has disappeared (Jorgensen et al., 1982).

Stoffel et al. (2017) published a consensus paper on the management of non-neurogenic urinary retention, defined as a postvoid residual above 300 mL that has persisted for at least 6 months and documents on at least two occasions and is classified as high or low risk and symptomatic or asymptomatic. After a thorough history and physical examination, if a high-risk variable is present, such as hydronephrosis, hydroureter, chronic kidney disease, recurrent UTI, or urinary incontinence with skin sequalae, then treatment with bladder drainage, either intermittent catheterization or indwelling catheter, is recommended. If patient is experiencing symptoms, the underlying cause should be targeted for treatment. If long-term catheterization is required, it was the authors’ opinion that suprapubic catheter is preferable to urethral. Importantly patients with chronic urinary retention must be followed long term to assess for changes and mitigate any high-risk factors.

Bladder Neck Dysfunction

Bladder neck dysfunction is defined here as **an incomplete opening of the bladder neck during voluntary or involuntary voiding.** It has also been referred to as *smooth sphincter dyssynergia, proximal urethral obstruction, primary bladder neck obstruction,* and *dysfunctional bladder neck.* **The term *smooth sphincter dyssynergia* or *proximal sphincter dyssynergia* is usually used when referring to this urodynamic finding in an individual with autonomic hyperreflexia.** In male patients with autonomic hyperreflexia, the neurologic pathophysiology is clear. **The term *bladder neck dysfunction* more often refers to a poorly understood, non-neurogenic condition first described more than a century ago but first fully characterized by Turner-Warwick et al. in 1973. The dysfunction is found almost exclusively in young and middle-aged men, who characteristically report long-standing voiding and storage symptoms** (Norlen and Blaivas, 1986; Trockman et al., 1996; Webster et al., 1980; Wein and Barrett, 1988; Yamanishi et al., 1997). **These patients have often been seen by many urologists and have been diagnosed as having psychogenic voiding dysfunction because of a normal prostate on rectal examination, a negligible residual urine volume, and a normal endoscopic bladder appearance.** The differential diagnosis also includes anatomic bladder neck contracture, benign prostatic enlargement (BPE) or BPO, dysfunctional voiding, prostatitis, neurogenic micturition dysfunction, and low pressure and low flow. **Objective evidence of outlet obstruction in these patients is easily obtainable by urodynamic study. Once obstruction has been diagnosed, it can be localized to the level of the bladder neck by videourodynamic study, cystourethrography during a bladder contraction, or micturitional urethral profilometry.** The diagnosis may also be made indirectly by the urodynamic findings of outlet obstruction in the absence of urethral stricture, prostatic enlargement, and DSD. Noble et al. (1994) cited the incidence of concomitant involuntary bladder contractions or decreased compliance as 50%; Trockman et al. (1996) quoted it as 34%.

The exact cause of this problem is unknown. Some have proposed that there is an abnormal arrangement of musculature in the bladder neck region, such that coordinated detrusor contractions cause bladder neck narrowing instead of the normal funneling (Bates et al., 1975). The occurrence of this problem in young, anxious, and “high-strung” individuals, and its partial relief by α-adrenergic blocking agents, have prompted some to speculate that it may in some way be related to sympathetic hyperactivity.

When prostatic enlargement develops in individuals with this problem, a double obstruction results, and Turner-Warwick (1984) has coined the term *trapped prostate* to describe these patients. Because the lobes of the prostate cannot expand the bladder neck, they expand into the urethra. In general, a patient so affected has a lifelong history of voiding dysfunction that has gone relatively unnoticed because he has always accepted this as normal, and exacerbation of these symptoms may occur during a relatively short and early period of prostatic enlargement. Although α-adrenergic blocking agents provide improvement in some patients with bladder neck dysfunction, definitive relief in men is best achieved by a bladder neck incision. In patients with this and a trapped prostate, marked relief is typically effected by a small prostatic resection or ablation that includes the bladder neck, or a transurethral incision of the bladder neck and prostate. Such patients often note afterward that they have “never” voided as well as after their treatment.

Bladder Outlet Obstruction in Women

The female counterpart of male non-neurogenic bladder neck dysfunction is rare but does exist. **Bladder outlet obstruction in women in general is uncommon.** Diokno et al. (1984) were among the first to clearly define this entity in women on the basis of video-urodynamic studies. Nitti et al. (1999) evaluated the videourodynamic studies of 261 of 331 women who underwent multichannel studies for non-neurogenic voiding dysfunction. **They defined *bladder outlet obstruction* as radiographic evidence of obstruction between the bladder neck and the distal urethra in the presence of a sustained detrusor contraction of any magnitude, which is usually associated with reduced or delayed urinary flow rate. Obstruction at the level of the bladder neck was diagnosed when the bladder neck was closed or narrowed during voiding. Obstruction of the urethra was diagnosed as a discrete area of narrowing associated with proximal dilation.** Strict pressure-flow criteria were not used to classify cases as obstructed or not obstructed. Using these criteria, the authors found 76 (23%) of their cases to be obstructed and of those, only 12 (16%) were diagnosed as having primary bladder neck obstruction (the counterpart to non-neurogenic bladder neck dysfunction in the male). Thirty-three percent of the cases of obstruction were caused by dysfunctional voiding, 28% by cystocele, 14% by obstruction created by prior incontinence surgery, 4% by urethral stricture, 3% by uterine prolapse, and 1% each by urethral diverticulum and rectocele. Groutz et al. (2000) **defined obstruction as a persistent low, noninvasive maximum flow rate less than 12 mL/ sec on repeated study combined with a detrusor pressure at maximum measured flow rate of more than 20 cm H_2O in a pressure-flow study.** Of the 587 consecutive women referred for urodynamic evaluation of voiding symptoms, only 38 (6.5%) met these criteria of bladder outlet obstruction. Of those, only 3 women (8%) were characterized as having primary bladder neck obstruction. Ten women (26%) had obstruction on the basis of prior anti-incontinence surgery, 24% because of severe genital prolapse, 13% because of urethral stricture, 5% because of dysfunctional voiding, 5% because of true DSD, and 3% because of urethral diverticulum; in 16% there was no identifiable cause. A new nomogram for defining bladder outlet obstruction in women was introduced by Solomon et al. (2017) based on video urodynamic and clinical data of 185 women and then validated the nomogram on 350 women. This nomogram uses Qmax (maximum flow rate) and Pdet@Qmax (detrusor pressure at maximum flow) to determine the probability of obstruction and showed very good agreement with Nitti's nomogram, which relies on urodynamic parameters in addition to fluoroscopy findings to determine obstruction.

Most authors would agree that surgical treatment of this problem in women should be approached with caution because sphincteric incontinence is a significant risk. Smith and Appell (2006) commented on the importance of urodynamics in distinguishing dysfunctional voiding versus bladder neck dysfunction. They commented on the importance of evaluation inclusive of symptom assessment, uninstrumented uroflow patterns, simultaneous urodynamic and electromyographic assessment of voiding, as well as the addition of fluoroscopy to assess function of the bladder neck during voiding. They further stressed multidisciplinary therapy including pelvic floor therapy (biofeedback), behavioral modification, and the addition of pharmacotherapy.

Pelvic organ prolapse (POP), particularly if high grade, can anatomically result in bladder outlet obstruction from urethral kinking. Hoffman and Nitti (2016) reported that 58% of patients with high-grade POP can experience obstructive voiding. It is important to assess improvement in obstruction and associated symptoms with reduction of the prolapse before surgical correction. Up to 94% will have improvements in maximum flow rate with correction of POP.

Low-Pressure and Low-Flow Voiding in Younger Men: Paruresis (Bashful Bladder)

Low-pressure and low-flow voiding **can be the result of a number of causes, most notably a decompensating detrusor** (usually from bladder outlet obstruction) or as a part of the syndrome known as *detrusor hyperactivity with impaired contractility* (DHIC). **When this occurs in a young man, it is usually characterized by frequency, hesitancy, and a poor stream.** The entity is readily demonstrated on urodynamic assessment and with no coexisting endoscopic abnormality. **The patient usually notes marked hesitancy when attempting to initiate micturition in the presence of others, called paruresis,** although more often referred to as a “shy bladder” or a “bashful bladder.” The estimate of the incidence of this problem in younger male patients referred for urodynamic assessment varies from 2.8% (Hammelstein et al., 2005) to 19% (George and Slade, 1979).

Barnes et al. (1985) suggested that, psychologically, these men tend to be obsessional rather than anxious. They suggest that these individuals have a lifelong tendency to over-control the process of micturition and are thus vulnerable to LUTS under stress. The authors recommend that a behavioral modification program be considered. Rosario et al. (2000) performed ambulatory urodynamic studies on 40 consecutive symptomatic men with a mean IPSS of 19 who were unable to “perform” during conventional videourodynamic study. They concluded that a surgically correctable cause of the symptoms could be found in only 20% of men, and only in those 40 years of age and older. They concluded that the contribution of ambulatory urodynamic monitoring in such cases in men younger than 40 years was negligible. As with previous studies, these authors thought that a significant proportion of such nonobstructed cases would respond to drug therapy or behavioral intervention. Furthermore, Kuoch et al. (2017) performed a systematic review and found that many with paruresis suffer from comorbid psychological disorders, specifically 29% had anxiety disorder and 22% had major depressive episodes suggesting that treatment may also require psychological intervention.

Urinary Retention: Fowler Syndrome in Young Women

Although urinary retention is encountered fairly commonly in men with anatomic obstruction from BPE, urinary retention in women is unusual but not rare. As in men, **the potential causes are classically cited as neurologic, pharmacologic, anatomic, myopathic, functional, and psychogenic.** A comprehensive review and algorithm for evaluation and treatment of the various causes of urinary retention in women has been published by Smith et al. (1999).

Fowler syndrome (Fowler, 1999, 2003; Fowler et al., 1988; Noble et al, 1994; Swinn and Fowler, 2001) is **urinary retention in young women in the absence of overt neurologic disease. The typical history is that of a woman younger than 30 years who is unable to void for a day or more with no urinary urgency but increasing lower abdominal discomfort. A bladder capacity of more than 1 L with no sensation of urgency is necessary for the diagnosis. There are no neurologic or laboratory features to support a diagnosis of any neurologic disease.** MRI scans of the brain and the entire spinal cord have been reported to be normal. However, a MRI assessment of patients with Fowler syndrome has suggested exaggerated cortical procontinence behavior attributable to increased afferent activity emanating from the urethra inhibiting bladder afferents at the sacral level. This increased afferent activity is partially modulated by successful sacral neuromodulation resulting in decreased overall sphincteric activity (Griffiths and Fowler, 2010).

On concentric needle electrode examination of the striated muscle of the urethral sphincter, however, Fowler et al. (1988) described a unique electromyographic abnormality. This abnormal activity, localized to the urethral sphincter, consists of a type of activity that would be expected to cause inappropriate contraction of the muscle. Sphincter activity consists of two components: complex repetitive discharges and decelerating bursts. This abnormal activity impairs sphincter relaxation. These patients often have polycystic ovaries, raising the possibility that the activity is linked in some way to impaired muscle membrane stability. This, in turn, allows direct spread of electrical impulses throughout the muscle, possibly from a hormonal abnormality. Thus the disorder may possibly be the manifestation of a focal, hormonally dependent “channelopathy.” This would potentially explain why the condition is seen only in premenopausal women. Efforts to treat this condition by hormonal manipulation, pharmacologic therapy, or injections of onabotulinumtoxinA have been unsuccessful. This condition is highly responsive to neuromodulation, with a success rate approaching 70% even in women who have had urinary retention for many months or years.

The urodynamic finding is detrusor acontractility; however, the same electromyographic abnormality is found sometimes in women with obstructed voiding. This type of electromyographic activity is not uncommon; FitzGerald et al. (2000) cite an incidence of 8% in a series of women undergoing routine urodynamic and electromyographic studies, but its correlation with complete retention is relatively rare.

In one of the largest reports of Fowler syndrome, 247 women with a presumptive diagnosis of Fowler syndrome were assessed. Overall, the diagnosis was confirmed in 57.5% of patients. However, distressingly, in 32% of patients the authors were not able to determine an ultimate diagnosis. Of the study group, 4.8% had congenital intestinal pseudo-obstruction (associated in some patients with ingestion of high-dose opiates). Other cases of voiding dysfunction included detrusor failure (1.6%), pain or structural abnormality in the LUT (1.6%), recurrent obstruction after surgery for sphincteric incontinence (1.2%), and a neurologic abnormality other than Fowler syndrome (1.2%). The authors based their diagnosis on the classic Fowler syndrome (nonpainful urinary retention in women 20 to 35 years of age); patients frequently had polycystic ovaries and relatively mild LUT dysfunction. They further identified urodynamic findings including a very high urethral closure pressure (greater than 100 cm H_2O) and increased sphincter volume based on ultrasonographic assessment, perhaps suggesting a hormonal-based effect on channel receptors. The authors reported a success rate of 40% to 68% for peripheral nerve evaluation with neuromodulation, followed by a 60% complete success rate after formal implantation and an additional 14% partial success rate in their population. The possibility of autonomic dysfunction as being contributory to this condition was also raised (Kavia et al., 2006).

De Ridder et al. (2007) reported 62 women who underwent sacral nerve stimulation, 30 of whom had findings compatible with Fowler syndrome and 32 with idiopathic retention. Somatoform disorder was found in 26% of the Fowler syndrome patients and 43.8% of the idiopathic group. Depression was also higher in the Fowler syndrome group (30% vs. 18.8%). Neither of these findings, however, had correlation with outcome. Nine patients with Fowler syndrome (compared with 19 patients without Fowler syndrome) failed neuromodulation. The authors concluded that Fowler syndrome was actually a positive predictive factor for SNS response in patients with female urinary retention.

Postoperative Urinary Retention

Postoperative urinary retention is a well-recognized but poorly understood event. Its reported incidence is highly variable, between 5% to 70%, with many factors affecting rates (Baldini et al., 2009). It occurs more frequently after LUT and perineal, gynecologic, and anorectal surgery. In the placebo arms of four trials of adrenergic blocker prophylaxis after these types of surgery, the incidence of postoperative retention ranged from 18.8% to 57% (Velanovich, 1992). **Although not mutually exclusive, contributing factors include the following:**

1. Traumatic instrumentation
2. Bladder overdistention
3. Diminished awareness of bladder sensation
4. Decreased bladder contractility
5. Increased outlet resistance
6. Decreased micturition reflex activity
7. Nociceptive inhibitory reflex
8. Preexistent outlet pathology (e.g., BPH)

Anesthesia and analgesia can contribute to factors 2, 3, 4, and 6. The idea of a nociceptive inhibitory reflex initiated by pain or discomfort is an attractive one, because a sympathetic efferent limb could directly affect factors 4, 5, and 6.

Bladder decompression for 18 to 24 hours postoperatively decreased the incidence of retention in patients undergoing joint replacement surgery by 52% versus 27% (Michelson et al., 1988) and 65% versus 0 (Carpiniello et al., 1988), compared with CIC. The incidence of urinary infection with continuous catheterization was no different in the study by Michelson et al. (15% vs. 11%) and was less in the study by Carpiniello et al. (16% vs. 43%) in which CIC was carried out in the recovery room as well. The avoidance of acute bladder overdistention to prevent postoperative urinary retention is supported by the experimental observation of a reduced bladder response to sacral neural stimulation during overdistention (>80% reduction) and, as well, after overdistention (19% reduction) (Bross et al., 1999).

Historically, prophylactic adrenergic blockade with phenoxybenzamine has seemed effective in decreasing the incidence of postoperative retention. Velanovich (1992) performed a meta-analysis on the use of phenoxybenzamine and concluded that this agent reduced the occurrence by 29.1%. In a retrospective review of colorectal patients treated with and without phenoxybenzamine, Goldman et al. (1988) found a 54.7% incidence of retention in patients not given this agent versus a 19.2% incidence in those who were. The regimen for those not catheterized preoperatively was 10 mg orally the evening before and 1 hour before surgery, 2 hours after, and 10 mg twice daily for 3 days. For those who were catheterized before the procedure, the regimen was 10 mg twice daily, initiated the day before catheter removal. The mechanism of action is uncertain. If an inhibitory nociceptive reflex is initiated, and this is similar to the sympathetic reflex elicited by bladder filling (see Chapter 69), the mechanism is likely multifactorial. Alternatively, the drug may act only on the outlet to decrease resistance, which may be pathologically increased by anxiety, pain, and other factors related to surgery.

Whether other adrenergic blockers are as effective is uncertain (Cataldo and Senagore, 1991). A study of 95 men undergoing spinal surgery were randomized to alpha-blockage therapy 48 hours before surgery, specifically tamsulosin, or placebo, and there was no difference in postoperative urinary retention (Basheer et al., 2017). Although rare, urinary retention after spinal surgery must be distinguished from postoperative cauda equina syndrome resulting from epidural hematoma, which in addition to urinary retention is associated with saddle anesthesia and leg weakness.

Hyperthyroidism

Patients with thyrotoxicosis often have symptoms caused by sympathetic overactivity and autonomic nervous system imbalance. Hyperthyroidism has an association with LUTS, especially in women. Autonomic dysfunction may play a contributory role. In an assessment of 65 newly diagnosed untreated women with hyperthyroidism compared with 62 age-matched controls, the women with hyperthyroidism demonstrated significantly higher mean symptom scores for incomplete emptying, frequency, straining, and overall total symptoms. More than 80% demonstrated high total symptom scores and diminished peak flow rates. In follow-up, LUTS and flow times improved significantly after therapy.

There is no relationship between LUTS and serum thyroid levels, hormone levels, or other hyperthyroid symptoms (Ho et al., 2011). Goswami et al. (1997) reported that 12 of 30 patients (40%) experienced the onset of voiding symptoms 1 to 6 months after the onset of the symptoms of thyrotoxicosis. Four of these patients had enuresis. Of the 5 patients who underwent urodynamic studies, all had reduced flow rates, and 4 had a significant postvoid residual volume, 3 of whom had an enlarged bladder capacity and increased perineal electromyographic activity during voiding. The LUT dysfunction and urodynamic abnormalities resolved after resolution of the hyperthyroidism. The bladder symptoms were more common in females than in males. A higher incidence of bladder symptoms was noted in patients with thyrotoxicosis: a 7% incidence of urgency with or without hesitancy and a 1% incidence of enuresis.

Schizophrenia

Bonney et al. (1997) proposed that a significant subset of schizophrenic patients have involuntary bladder contractions secondary to brain pathology. In a previous study (Gupta et al., 1995), the same group demonstrated involuntary bladder contractions in 4 of 10 evaluable patients with schizophrenia who were referred because of voiding dysfunction or incontinence. All of these patients had a history of significant childhood incontinence, urge incontinence, bedwetting, and a diminished bladder capacity. In the later report (Bonney et al., 1997), the prevalence of urinary incontinence and related symptoms in a group of patients with chronic schizophrenia was compared with that of a group of comparable patients hospitalized with mood disorders. There was a significantly higher prevalence of urge incontinence (34% vs. 17%) and bedwetting (46% vs. 20%) in the group with schizophrenia, whereas there were no significant differences in urinary urgency, overall voiding dysfunction, fecal incontinence, or sexual dysfunction. The hypothesis of a neurobiologic correlation between schizophrenia and the occurrence of involuntary bladder contractions is an intriguing one. Another hypothesis is that treatment of schizophrenia with antipsychotics may cause urinary incontinence primarily via α-adrenergic blockade and a hypodopaminergic state. In a study of 8 patients on antipsychotic medications underwent urologic evaluation with urodynamic studies. The most common symptom was urinary urgency in 6 (75%) followed by nocturnal enuresis in 4 (50%) and five patients (62.5%) had detrusor overactivity on urodynamic evaluation (Sinha et al., 2016). It is possible that patients with psychotic disorders have bladder dysfunction related to the primary disease process and as a result of the medical treatment for their disorder.

Gastroparesis

Gastroparesis is a condition characterized by symptoms from impaired transit of intraluminal gastric contents into the duodenum in the absence of mechanical obstruction. It may be caused by diabetes, occur after gastric surgery, or be idiopathic. Goldman and Dmochowski (1997) characterized the voiding dysfunction of 17 patients with gastroparesis who were referred because of voiding symptoms, 10 of whom had idiopathic gastroparesis and in 7 of whom the condition was secondary to diabetes. Seven patients had abnormal detrusor contraction and delayed sensation, 5 had poor detrusor function and normal sensation, 3 had normal detrusor function and poor sensation, and 2 had normal detrusor contraction and sensation. There was no difference in the occurrence of the dysfunctions between the two groups. Predominant symptoms were urinary frequency in 7 and difficulty emptying in 10. Patients with idiopathic gastroparesis were more likely to note difficulty emptying (70%), whereas those with diabetic gastroparesis were more likely to have urinary frequency (71%). The authors postulated an association between idiopathic gastroparesis and bladder dysfunction and proposed that a common autonomic neuropathic syndrome may account for the bladder dysfunction in the idiopathic and the diabetic forms of this syndrome.

Myasthenia Gravis

Any neuromuscular disease that affects the tone of the smooth or striated muscle of the distal sphincter mechanism can predispose an individual to a greater chance of urinary incontinence after even a well-performed transurethral or open prostatectomy. Myasthenia gravis is an autoimmune disease caused by autoantibodies to acetylcholine nicotinic receptors. This leads to neuromuscular blockade and subsequent weakness in a variety of striated muscle groups. The incidence of incontinence after prostatectomy is indeed greatly increased in patients with this disease (Greene et al., 1974; Khan and Bhola, 1989). In addition, Sandler et al. (1998) reviewed three cases of de novo voiding dysfunction in patients with myasthenia gravis (one woman with intrinsic sphincter deficiency, poor pelvic muscle contractility, and detrusor overactivity; one man with detrusor hyporeflexia who reported urgency and incontinence; and one young woman with an acontractile bladder). The authors add a personal report of a fourth patient with urinary retention from detrusor areflexia. They hypothesize that such autonomic dysfunction in a patient with myasthenia may indicate a unique subset with a worse prognosis. There have been documented reports of successful treatment of OAB in patients with myasthenia gravis with intradetrusor onabotulinumtoxinA (Wright et al., 2016b) and percutaneous tibial nerve stimulation (Antoniou et al., 2016) without change in neurologic symptoms.

Isaacs Syndrome

Isaacs syndrome is a rare neurologic disorder characterized by continuous muscle contraction, fasciculations, myokymia, excessive sweating, and elevated creatinine kinase level. It is caused by antibodies possibly directed against potassium channels on peripheral nerves and is associated with peripheral neuropathy, autoimmune diseases, malignancies, and endocrine disorders. Tiguert et al. (1999) presented a case with urinary retention associated with a picture of acute demyelinating neuropathy. Their patient had painful urinary and fecal retention; the urinary retention was thought to be caused by spasm of the periurethral striated sphincter and was diagnosed by an inability to pass a catheter beyond this area. Rectal sphincter spasm was also diagnosed. The condition was treated with plasmapheresis and pharmacologic agents to relax the skeletal muscle. Suprapubic drainage was instituted. The condition subsided, and normal urinary function was ultimately restored.

Wernicke Encephalopathy

Wernicke encephalopathy is a rare but well-documented condition caused by a deficiency in thiamine (vitamin B_1) in alcoholic and nonalcoholic populations. Pathologic lesions are characteristically distributed periventricularly at the levels of the third and fourth ventricles, including the mammillary body, medial thalamic nucleus, hypothalamus, superior cerebellar vermis, PAG, and mid-brain tegmentum. The two major clinical manifestations of thiamine deficiency involve the cardiovascular and neurologic systems, with the latter manifesting in general as a peripheral neuropathy, also known as Wernicke encephalopathy. The initial symptoms of the polyneuropathy range from burning feet to muscle weakness. Sakakibara et al. (1997b) report a case of a pregnant woman with multiple neurologic manifestations of central and peripheral neuropathy and urgency incontinence, manifesting urodynamically with involuntary bladder contractions and a decreased bladder volume. **Resolution of the urinary symptoms occurred after thiamine replacement.** The authors hypothesized that lesions in the medial thalamic-hypothalamic area and PAG were primarily responsible for the micturitional disturbance. Tjandra and Janknegt (1997) reported a case of a man with chronic alcoholism with seemingly isolated erectile and voiding dysfunction. The emptying complaints correlated with a prolonged void with a peak flow rate of 6.4 mL/sec and an interrupted pattern during flowmetry, suggesting poor detrusor contractility. The erectile dysfunction was determined to be neurogenic, and both resolved with thiamine replacement.

Systemic Sclerosis (Scleroderma)

Scleroderma is a disease of the connective tissue characterized by thickening and fibrosis of the skin, abnormalities of the small arteries, and involvement of the gastrointestinal tract, heart, lung, and kidneys. The pathogenesis is unknown but thought to be caused by overexpression of the collagen gene DNA that contributes to excessive production of collagen in these patients. Lazzeri et al. (1995) reported the urodynamic assessment and histologic evaluation of 9 such women, of whom 5 had hesitancy, 4 had decreased stream, 2 had frequency and nocturia, and 2 had suprapubic pain. Four patients had detrusor areflexia, 1 of whom also had decreased compliance. Another patient with a decreased stream also had decreased compliance. Three of the patients with areflexia demonstrated collagen accumulation on histologic examination of bladder biopsies. The authors reviewed 5 literature reports of various aspects of LUT function and histology in patients with scleroderma but failed to find a consistent pattern. They hypothesized that the areflexia resulted from impaired neurologic modulation because of the histologic changes in the detrusor tissue.

Conversely, Minervini et al. (1998) evaluated 23 females with systemic sclerosis and found urodynamic alterations in only 3 of 9 patients who reported urinary symptoms. They were unable to correlate voiding symptoms, urodynamic changes, and the degree of bladder wall fibrosis or visceral involvement. Evidence of autonomic nervous system dysfunction was found outside the urinary tract in 13 of these patients. The authors speculate that when LUT dysfunction occurs, it could be caused by the fibrotic replacement of bladder smooth muscle. However, they did not exclude some degree of autonomic dysfunction, as well.

Ehlers-Danlos Syndrome

Ehlers-Danlos syndrome refers to a heterogeneous group of disorders characterized by inherited abnormalities of connective tissue. The main clinical manifestations are skin fragility, skin hyperextensibility, and joint mobility. More than 10 subtypes of the syndrome have been defined based on clinical, genetic, and biochemical criteria. Bladder diverticula and VUR have been associated with this disorder. Tokhmafshan et al. (2017) found at least 30 reports of bladder diverticula in the literature, and it has been suggested that operative repair is characterized by a higher recurrence rate than would ordinarily be expected. Deveaud et al. (1999) reported on one such patient with a large left-sided, non-emptying diverticulum, along with a greatly enlarged bladder capacity and high postvoid residual urine volume. Simultaneously, they reported a second patient without Ehlers-Danlos syndrome who had a UTI and left pyelonephritis. This patient also reported a decreased force of stream, and evaluation disclosed left VUR with a left (presumably congenital) periureteral diverticulum. The diverticulum enlarged with voiding, and the patient had a high postvoid residual volume. Both patients were successfully treated surgically. The authors thought the tissue from the non-periureteral diverticulum was more closely related to the pathophysiology of Ehlers-Danlos syndrome, noting the tissue from that diverticulum to be more compliant. They attributed this to changes in the extracellular matrix protein caused by the Ehlers-Danlos syndrome.

Myotonic Dystrophy

Myotonic dystrophy is an autosomal dominant hereditary multi-organ disease characterized by myotonia and distal muscle atrophy. In addition, this condition in later stages is characterized by cataracts, endocrine disturbances, mental retardation or dementia, testicular atrophy and infertility, progressive frontal alopecia, and disturbances in cardiac conduction. Although myotonic activity has not been found in the sphincter or pelvic floor, many patients have voiding complaints. Bernstein et al. (1992) reported on 10 patients, 8 of whom had urinary complaints by history (4 infrequent voiders, 1 with urgency and stress incontinence, 1 with urge and urgency incontinence, 1 with slight urgency without incontinence, and 1 with obstructive symptoms only in the morning). There were no characteristic urodynamic patterns observed, and urodynamic findings did not correlate particularly well with symptoms. Sakakibara et al. (1995b) also reported LUTS in such patients; however, there is **no characteristic pattern of dysfunction.** Thus such patients must be characterized urodynamically before any assumptions are made regarding therapy based on symptoms alone.

Corticobasal Degeneration

Corticobasal degeneration is a rare neurodegenerative disorder of the corticobasal tracts in the cerebral cortex and basal ganglia. The disorder tends to have a unilateral predominance and is most likely present in the supranuclear parasympathetic system. Cortical, extrapyramidal, long-tract, and urinary symptoms are commonly noted in this disease process. Sakakibara et al. (2004b) assessed 10 patients with this disorder and compared them with 11 age-matched controls. As compared with controls, the degeneration patients had more common urinary symptoms (80% of study group). Urinary symptoms usually appeared within 1 to 3 years after onset of the disease and became more common with longer disease duration. Nocturnal frequency tended to be the initial urinary symptom, followed by incontinence, urgency, and frequency. Urodynamic findings included decreased bladder capacity, detrusor overactivity (most common), detrusor hypocontractility, and low compliance in individual patients. DSD was not noted.

Sacrococcygeal Teratoma

Sacrococcygeal teratoma is the most common congenital neoplasm, can cause significant neurourologic dysfunction, and can be associated with upper tract deterioration as a result of high-grade reflux and abnormal bladder storage pressures. Partridge et al. (2014) retrospectively reviewed 45 patients who underwent resection for sacrococcygeal teratoma and found that urologic complications occurred in 33%, with neurogenic bladder in 12, urinary incontinence in 7, and vesicoureteral reflux in 5. The presence of hydronephrosis on prenatal imaging was significantly associated with urologic sequelae.

Williams-Beuren Syndrome

Williams-Beuren syndrome (WBS) is an autosomal disorder caused by a deletion in chromosome 7. It is associated with cardiovascular abnormalities, facial changes, cognitive dysfunction resulting in mental retardation, and developmental delay. LUTS is also highly prevalence in this population. In a study of 87 children (41 girls, 46 boys) with this syndrome, LUTS was assessed by questionnaire and all had a frequency-volume chart. Eighty percent of children had LUTS: urgency was the most common in 70%, followed by frequency in 69%, and urge incontinence in 61% (Sammour et al., 2017). In a smaller study of 28 children (16 boys, 12 girls) assessment included renal functional studies, voiding cystourethrography, and urodynamics. Fifty percent of patients had urinary tract abnormalities; bladder diverticula was the most common (43%). Urodynamic findings demonstrated detrusor overactivity in 60% of patients and sphincteric dyssynergia with detrusor overactivity in 14%. Decreased cystometric capacity was identified in 28% of patients (Sammour et al., 2006).

Amyloidosis

Subtypes of amyloidosis are associated with neurologic disorders. Type 1 Portuguese familial amyloid polyneuropathy is a rare, progressive, autosomal dominant disease characterized by autonomic and somatic dysfunction with early onset of gastrointestinal and genitourinary symptoms. In a study of 23 women gene carriers undergoing urodynamic evaluation, the presence of reduced bladder sensation and detrusor underactivity was higher in those with more advanced disease, although these symptoms were still present in 33% and 25%, respectively, of asymptomatic carriers. Bladder and anal sphincteric dysfunction also appears to occur early in the disease process. Stress incontinence often results, and the anal sphincter was found to have decreased tone (Andrade, 2009; Gomes et al., 2014). Impaired detrusor contractility is thought to be caused by amyloid infiltration of peripheral nerves.

Machado-Joseph Disease

A variant of spinocerebellar degeneration is spinocerebellar ataxia type 3, otherwise known as Machado-Joseph (MJ) disease. This is the most common hereditary spinocerebellar ataxia dominant disease. It is associated with a defined expansion of the *MJD1* gene from the 14q32.1 chromosome. Symptoms include pyramidal spasticity, extrapyramidal rigidity, athetosis, dystonia, visual movement disorder (ophthalmoplegia), eyelid retraction, amyotrophy, and impairment of global sensory function. In a study of 122 patients with this disorder, 17 (13.9%) experienced LUT dysfunction. The mean age of occurrence of the disease was the mid-fifth decade, with urgency being the predominant symptom in 15 and incontinence found in 9 patients. The most common urodynamic finding was detrusor overactivity in 8 patients, areflexia in 1, and normal contractility in 4. Bladder sensory disorder defined by delayed perceptions was identified in 6 patients. Postvoid residual volumes greater than 100 mL were noted in 9 (Musegante et al., 2011).

Radiation

Many pelvic neoplasms are treated with radiotherapy, and despite improved imaging and targeting techniques, nearby healthy tissue, such as the bladder, can be adversely affected. **An early radiation reaction, most prominent at 4 to 6 weeks,** is described by Vale et al. (1993). **Storage symptoms are common, and urodynamic studies have demonstrated reduced volume at first desire to void, reduced cystometric capacity, and reduced compliance. These parameters tend to return to pretreatment values by 6 months. Radiation effects on tissue evolve over time, and symptoms associated with later radiation effects are less common but may be progressive and intractable. Storage symptoms again predominate, and urodynamic studies, when positive, demonstrate reductions in first desire to void and maximum cystometric capacity, presence of involuntary bladder contractions in up to a third of patients, and an increase in maximum subtracted detrusor pressure during filling.** Historical explanations have concentrated on urothelial injury and ulceration with fibrosis. In an experimental rat model, the authors found a biphasic reduction in compliance, with the first reduction developing at 4 to 6 weeks after irradiation, followed by recovery. A second reduction phase in compliance started at 10 to 12 weeks and persisted. Only half of the irradiated bladders demonstrated fibrotic infiltration of muscle bundles, and there was no association between the presence of fibrosis and the magnitude of reduction and compliance. Mast cells were more abundant in irradiated bladders than in controls. Electron microscopic studies in the irradiated bladders showed the presence of areas displaying focal degeneration of smooth muscle cells, with these cells demonstrating disaggregation of filaments and, in some cases, cytoplasmic organelles free in the intracellular space. In scattered foci, selective degeneration of unmyelinated axon profiles was noted, ranging from marked to lesser degrees of axonal injury. Thus the authors were unable to confirm a fibrosis-based hypothesis of postirradiation bladder dysfunction in their experimental model but did reveal other changes that could contribute to such dysfunction (neural degeneration and changes in the detrusor muscle).

Choo et al. (2002) reported on videourodynamic parameters in 15 of 17 patients completing studies at baseline and at 3 and 18 months after external-beam irradiation for prostate cancer. Between baseline and 18 months there were no statistically significant changes in detrusor pressure, peak flow rate, voided volume, postvoid residual, compliance, occurrence of detrusor overactivity, or outlet obstruction. There was a mean reduction in bladder capacity of 100 mL in the supine position and 54 mL in the upright position. There was no change in self-assessed qualitative urologic function (IPSS, quality-of-life assessment index, and urinary frequency). There were, however, individual patients who developed decreased compliance (4 patients) and detrusor overactivity (2 patients), urgency (5 patients), and urgency incontinence (3 patients).

There has been a correlation shown between radiation dose received by the bladder from external beam radiotherapy for the treatment of prostate cancer and LUT symptoms, specifically incontinence and frequency (Yahya et al., 2017). Urinary tract effects secondary to radiation often require further management. In a study by Mayer et al. (2017) of 73 men receiving combined modality radiotherapy for prostate cancer, at a median time of 8 years from radiotherapy, 25% of men required reconstruction (ureteral n = 4, rectourethral fistula n = 2, and posterior urethroplasty n = 13) and 32% underwent urinary diversion, highlighting the significant long-term morbidity of radiotherapy.

Defunctionalized Bladder

The timing of bladder defunctionalization and the age of the individual at time of defunctionalization may be predictive of bladder functionality. In fetal sheep, urinary diversion results in loss of overall bladder weight with marked connective tissue infiltration and loss of smooth muscle organization. Also, a reduced response to carbachol stimulation and increased response to field stimulation were noted in tissue from animals undergoing early diversion (Matsumoto et al., 2003).

The previously normal defunctionalized bladder often demonstrates decreased capacity and involuntary bladder contractions and/or decreased compliance. Previously abnormal bladders will usually demonstrate their prior pathology, many times with these additional abnormalities. Rehabilitation of a defunctionalized bladder is certainly possible and should definitely be attempted by cycling with progressively increasing volumes. Serrano et al. (1996) considered this subject while evaluating the outcome of transplantation in five long-term defunctionalized bladders. Successful bladder rehabilitation was accomplished, and the transplantation was successful without bladder augmentation, although one patient required CIC. Normal compliance was inferred by the fact that there was no evidence of hydronephrosis after long-term allograft function up to 10 years. The authors proposed that transplantation can be accomplished into a previously defunctionalized bladder when a capacity greater than 100 mL and a voiding pressure less than 100 cm H_2O are demonstrated during bladder rehabilitation. The presence of a defunctionalized bladder may not prevent subsequent renal transplantation. In an assessment of 12 pediatric patients with markedly diminished-capacity (defunctionalized) bladders, transplantation was performed without pretransplant bladder augmentation. The overall transplant survival rates in this group were 100%. Minimal reflux was noted. In addition, all patients were able to void spontaneously without incontinence (Alexopoulos et al., 2011).

A study of bladder receptors at the gene expression level suggested no significant differences between pre-transplant patients with or without defunctionalized bladders, and voiding function was similar between the two groups at 1 year post-transplant, leading authors to question the usefulness of classifying bladders as defunctionalized pre-transplant (Neves Neto et al., 2018). These are interesting data; however, in appropriate patients an assessment of bladder function is prudent before renal transplant to ensure postoperative success given the high stakes.

Disorders of Sexual Differentiation

Disorders of sexual differentiation, such as congenital adrenal hyperplasia (CAH) or androgen insensitivity syndrome (AIS), may have effects on urinary symptoms as a result of feminizing surgery or a primary affect of the disorder. Davies et al. (2005) studied 19 women with CAH, of whom 16 had undergone childhood feminizing surgery. Compared with age-matched controls, the CAH population had a higher incidence of urgency incontinence (68%) and stress incontinence (47%). In a similar study, women with CAH or AIS found LUTS to be common in this population; however, they were not significantly increased compared with controls (Fagerholm et al., 2013). It remains uncertain the effects of disorders of sexual differentiation on urinary symptoms.

Aging

Structural changes of the autonomic pathways in normal aging may be at least partially responsible for bladder effects. Neurons in an aged animal model demonstrated terminal axonal dystrophy (Schmidt, 2002). In addition, decreases in muscarinic receptor expression within the detrusor may be a contributor to bladder dysfunction in normal aging (Mansfield et al., 2005). However, when the effects of aging on the LUT are considered, it is not possible to separate the effects of chronologic age itself from the various anatomic, neurophysiologic, neuropharmacologic, metabolic, and hormonal changes that coexist with aging, along with the effects of other coexistent disease processes.

In a study of 85 healthy females without a history of neurologic disease, pelvic surgery, or diabetes, there was an age-related decline in detrusor contractility, bladder sensation during filling, and maximum urethral closure pressure (Pfisterer et al., 2006). In addition, neurologic phenomena may masquerade as LUTS associated with bladder outlet obstruction. These phenomena may include multiple cerebral infarctions, cervical spondylosis, and lumbar spondylosis, all findings noted in the Olmsted County longitudinal study and indicative of the need for urodynamics in older men with complex urinary symptoms (Woderich and Fowler, 2006). There is an excellent review of this topic by the Committee on Pathophysiology of the Urinary Bladder and Obstruction and Aging for the 4th International Consultation on BPH (Nordling et al., 2001).

Benign Joint Hypermobility Syndrome

Benign joint hypermobility syndrome (BJHS) is an inherited connective tissue disease characterized by musculoskeletal pain and hypermobility of joints and has an apparent association with pelvic floor dysfunction. Manning et al. (2003) prospectively evaluated 1000 women referred for urodynamic evaluation and noted benign joint hypermobility to be associated with increasing bowel dysfunction and a higher degree of urinary tract symptomatology. Also noted was a significant childhood history for both of these phenomena. In a study of 38 women with joint hypermobility as compared with normal controls, symptom questionnaires were administered to both groups; 18 of 30 (60%) with benign joint hypermobility demonstrated urinary incontinence as compared with an incidence of 30% in the controls. In addition, 23% of the women with joint hypermobility also demonstrated anal incontinence as compared with none of the controls (Jha et al., 2007). In a pediatric population with BJHS, 60% had VUR; grade II was the most common, in 37.5% (Beiraghdar et al., 2013). These findings have been attributed to disorders of collagen metabolism; however, the absolute cause has not been clearly delineated.

Attention-Deficit/Hyperactivity Disorder

Attention-deficit/hyperactivity disorder (ADHD) occurs in 3% to 5% of children, and LUTS are common in this group. In a study of 62 children with ADHD and 124 controls, assessment of LUTS through a validated questionnaire indicated children with ADHD had significantly higher enuresis, urgency, holding maneuvers, and voiding and other symptoms (Burgu et al., 2011). Treatment of ADHD may result in improved LUTS, as a study of 40 children treated for ADHD and 43 matched controls showed that incontinence rates did not differ between the groups, although children with ADHD reached continence at an older age (Niemczyk et al., 2015).

Other Conditions

The effect of disordered function of other organs within the pelvis is also potentially contributory to LUT dysfunction. Some of this disordered function may arise as a result of altered afferent neurologic activity induced by other organ disorders. The potential for visceral “crosstalk” has been proposed as a cause of LUT dysfunction and includes syndromes such as interstitial cystitis and irritable bowel syndrome. Noronha et al. (2007) assessed the short- and long-term effects of acid-induced colitis on bladder function in a rodent model. Detrusor muscle contractility and histology were evaluated, acutely and subacutely after induction of chemical colitis. During the active phase (3 days postinjury), bladder muscle structure appeared histologically normal and inflammation was absent. However, some abnormalities in detrusor muscle contractility in response to electric field stimulation were noted. During the subacute period and after recovery of colitis (15 and 30 days), bladder muscle contractility returned to control levels with no discernible histologic change. These reversible changes were postulated to result from altered afferent input from the colon, resulting in “field” type changes affecting the bladder.

Any neurologic disease or injury can affect LUT function. Many have been mentioned in this chapter, but case reports and small series document many others. The dysfunction produced by some is logically deducible on the basis of similarity to other neurologic lesions. For others, the LUT dysfunctions are inconsistent and seemingly at odds with what would be predicted on the basis of neuroanatomic and neurophysiologic principles. For those who wish to further pursue this subject, the following referenced list may be helpful:

- Adrenoleukodystrophy, adrenomyeloneuropathy (Sakakibara et al., 1998a; Silveri et al., 2004)
- Adult polyglucosan body disease (Gray et al., 1988)
- Behçet disease (Saito and Miyagawa, 2000; Sakakibara et al., 2000; Theodorou et al., 1999)
- Brown-Séquard syndrome (Sakakibara et al., 2001)
- Central cord syndrome (Newey et al., 2000; Smith et al., 2000)
- Incontinence in cystic fibrosis (Dodd and Langman, 2005; Neemuchwala, 2017)
- Down syndrome (Handel et al., 2003)

- Spinal muscular atrophy (von Gontard et al., 2001)

Treatment of Neurogenic Lower Urinary Tract Dysfunction: Overview

In later chapters, the various therapies available for the treatment of LUT dysfunction are discussed. Only a discrete number of such therapies are available, and these are easily categorized on a functional basis according to whether they are used primarily to facilitate urine filling and storage or voiding and emptying and according to whether their primary effect is on the bladder or on the outlet.

The initial choice of a mode of management for a given problem is multifactorial, **and certain goals of management for LUT dysfunction are beyond debate** (Box 116.2). The fact that these goals have remained relatively unchanged over the past editions of this text attests to their general validity. As a corollary, absolute or relative indications for changing or augmenting a particular regimen exist, and, likewise, there is general agreement on these, although the relative importance of the indication for change may be disputed (Box 116.3). The term *inadequate*, when applied to storage and emptying, applies not only to volumes (capacity, voided volume, residual) but also to unacceptably high detrusor pressures during either or both of the two phases of the micturition cycle. In the planning of goals of therapy and reasons for change, the concept of a “hostility score,” such as that of Galloway (1989), is attractive. His hostility score includes five urodynamic characteristics—bladder compliance, overactivity, dyssynergia, outlet resistance, and VUR. Each is allocated a score of 0, 1, or 2. The best possible score is 0 and implies normal compliance, no inappropriate detrusor activity, a synergic sphincter, a low leak pressure, and no reflux.

Box 116.2

Voiding Dysfunction: Goals of Management

- Upper urinary tract preservation or improvement
- Absence or control of infection
- Adequate storage at low intravesical pressure

- Adequate emptying at low intravesical pressure
- Control over micturition
- No catheter or stoma
- Social acceptability and adaptability
- Vocational acceptability and adaptability

Box 116.3

Reasons to Change or Augment a Given Regimen

- Upper urinary tract deterioration
- Recurrent sepsis or fever of urinary tract origin
- Lower urinary tract deterioration
- Inadequate storage
- Inadequate emptying
- Inadequate control
- Unacceptable treatment side effects
- Skin changes secondary to incontinence or collecting device

The results of treatment of voiding dysfunction are rarely perfect, and they do not have to be. The goals are satisfaction and avoidance of adverse outcomes. A very flexible approach must be adopted in choosing therapy that takes into account the individual wishes of each patient and family and the practicality of each proposed solution for that particular patient (Box 116.4). The therapeutic decisions are thus made with the patient and with the family. In every case, within the limits of practicality, the following should be discussed: reversibility, side effects that occur with some regularity, ultimate best and worst possible scenario, frequency and extent of follow-up, and alternate methods of management. Treatment should always begin with the simplest, most reversible form(s) of therapy, proceeding gradually up the ladder of complexity, but with the knowledge that it is only the patient (and/or family) who is (are) empowered to say when “enough is enough.” Again, satisfaction and avoidance of adverse outcomes are the primary goals. A combination of therapeutic maneuvers can sometimes be used to achieve a particular end, especially if these modalities act through different mechanisms and their side effects are not synergistic or additive. There are circumstances and locales in which health care resources and hospital bed use must also be considered.

Box 116.4

Patient Factors to Consider When Choosing Therapy

- Prognosis of underlying disease, especially if progressive or malignant
- General health
- Limiting factors: inability to perform certain tasks (e.g., hand dexterity, ability to transfer, body habitus)
- Mental status
- Motivation, patient compliance with treatments
- Desire to remain catheter or appliance free
- Desire to avoid surgery
- Sexual activity status
- Reliability
- Educability
- Psychosocial environment, interest, reliability, and cooperation of family
- Economic resources

The importance of graded intervention for neurogenic disease with the ultimate goals of control of bladder pressures, preservation of renal function, control of UTI, and social continence has been underscored by two guidelines (Consortium for Spinal Cord Medicine, 2006; Pannek et al., 2011). Bladder management options include catheterization (intermittent or indwelling) and surgery. Consensus guidelines stress the importance of intermittent catheterization as the foundational strategy in the management of the willing and motivated patient or health care provider with the goal of keeping catheterization volumes below 500 mL. Credé or Valsalva is not a recommended technique for improving bladder emptying, given concerns regarding outlet resistance. When chronic catheterization is required, suprapubic management is preferable to indwelling urethral catheterization. However, CIC remains the gold standard (EAU guidelines). The basis of progressive therapy from medical ascending through surgical is a foundational concept (Wyndaele et al., 2010). An ongoing multi-institutional study by the Neurogenic Bladder Research Group (study protocol: Patel et al., 2017) comparing various bladder management strategies will shed light on patient outcomes, satisfaction, and quality of life; help guide physician-patient discussions; and improve informed decision making.

Urodynamics may provide a useful guide for directing intervention. Differences in bladder compliance may be predictive of intervention success. Type A (total) versus type C (end fill) compliance patterns respond differently to antimuscarinic management, with resultant impacts on bladder storage pressures and upper tract function (Park and Linsenmeyer, 2001).

Optimal management of the bladder in spinal cord injuries has, in general, focused on the use of CIC where available. In a study of 179 patients undergoing management either with suprapubic or urethral catheterization, both groups had complications related to management technique. Tube revision and incontinence through the suprapubic tract were common in the group so managed. In the urethral management group, urethral erosion and incontinence were also common. The rates of UTI, bladder calculi, and bladder cancer were similar between the two groups (Katsumi et al., 2010). A prospective randomized assessment of spinal cord–injured patients using CIC was performed to address the rate of UTI with this condition. The time to first UTI requiring antibiotic management was significantly lengthened in patients using hydrophilic-coated catheters as compared with uncoated catheters. A 33% daily risk for symptomatic infection in those using the hydrophilic catheters was identified. In institutional settings, the use of these catheters reduced infection rate by approximately 21% (Cardenas et al., 2011).

Medical therapy is first-line treatment for NDO; anticholinergic medications are the most studied. Mirabegron, a selective β3 agonist, has also demonstrated efficacy in NDO (Wollner and Pannek, 2016). In patients with NDO refractory to medications or patients intolerant to the medication side effects, treatment with intradetrusor onabotulinum toxinA injection has shown good therapeutic results with up to 60% of patients continuing with this treatment over the long term (Leitner et al., 2016).

The treatment of DSD is challenging. Although limited to select male patients, when sphincter ablation is necessary, sphincterotomy using laser treatment is considered the standard method (Linsenmeyer, 2007). However, there is an emerging role of onabotulinum toxin A intra-sphincteric injection, which has been shown to lower detrusor pressures and increase voided volumes and has low morbidity, although repeated injections are needed (Utomo et al., 2014).

New therapies continue to be proposed for patients with neurogenic LUT dysfunction refractory to medical therapies. The use of dorsal penile or clitoral nerve stimulation for controlled NDO has been described. Opisso et al. (2008) studied a group of 17 patients with neurologic disorders (4 women and 13 men) who underwent 3 filling cystometries. With stimulation of the dorsal nerve, 16 were noted to have suppression of detrusor contractions and 14 had an average increase in bladder capacity of 68 mL. Larger studies with longer follow-up are needed to assess long-term effectiveness and durability.

Pudendal nerve stimulation has been used for improving neurogenic voiding dysfunction. Spinelli et al. (2005) treated 15 patients with varied types of neurogenic voiding dysfunction. After pudendal stimulation, there was a significant decrease in incontinence episodes: 8 of 15 patients became continent during stimulation, and 2 demonstrated improvement approximating 90%. Twelve of 15 ultimately progressed to permanent implantation. In the chronically implanted patients, maximal cystometric capacity was noted to significantly increase, and maximum detrusor pressure was also noted to decrease substantially. Neurophysiologic guidance was considered critical for adequate implantation.

Another form of neuromodulatory therapy for which more experience is being reported in SCI is anterior root stimulation. One of the largest experiences with sacral deafferentation and anterior root stimulator implantation was reported by Kutzenberger et al. (2005). A total of 464 paraplegic patients received this intervention, with most patients receiving the intradural approach. At a mean of 6.6 years, 440 of these patients were available for long-term follow-up. Complete deafferentation was successful in 94% of patients; 420 patients used the sacral anterior root stimulator for voiding, and 401 used it for defecation. Overall, 364 (83%) patients were continent. Postoperatively, UTIs decreased from a mean of 6 to 1, and kidney function remained stable in this population. Complications included cerebrospinal fluid leaks in 6 patients and infected implants in 5. In addition, later complications included device failure or cable failure in 35 patients. Autonomic dysreflexia also disappeared or was resolved in most of these cases. The Dutch experience with the Brindley bladder stimulator compared with a matched control group was reported; 93 stimulator-implanted patients were compared with a control group of 70 new patients with SCI and NDO. The main outcomes in the study were quality of life as assessed by the Qualiveen metric. In those patients implanted, long-term stimulators were still used for voiding dysfunction in 63% of the patients (46 patients). Those patients with functional stimulator implants had substantially improved symptom scores and general quality-of-life ratings in addition to improved continence and fewer UTIs as compared with the control group. The associated rhizotomy appeared to benefit even patients who had deactivated their stimulator device. The follow-up for these individuals after implant ranged from 1 to 3 years (Martens et al., 2011).

Bladder reinnervation is an upcoming area of study. Unilateral lumbar to sacral ventral root rerouting surgery has demonstrated success in axonal regrowth and restoration of bladder function in a feline model with complete thoracic spinal cord injury (Lam Van Ba et al., 2018). The future of urinary tract dysfunction related to SCI may be dependent on advances in the use of stem cells for spinal cord repair. However, differences in study type, model used, type of stem cells, and techniques used for stem cell implantation and perpetuation have yet to be standardized for purposes of assessing the potentials of this therapy for impact on long-term urinary function (Snyder and Teng, 2012).

As a nonsurgical alternative to catheterization, women with detrusor areflexia can consider using the inFlow device, which is a magnetized valve-pump device inserted into the urethra. During voiding, an activator is held over the pubic bone and turned “on” to open the valve and allow urine flow. Once the bladder is empty, the “on” button is released and the valve closes, allowing urine storage. In a multicenter trial, those women who completed the study reported significant improvements in quality of life (Chen et al., 2005). However, there was a high drop-out rate because of patient discomfort and leakage. This device may have a role in those patients who are unable to catheterize.

As a treatment of last resort, urinary diversion may provide significant functional improvement in addition to improved quality of life in selected patients with neurologic dysfunction (e.g., those unable to catheterize). One method for management of incontinence or other refractory storage issues related to neurogenic bladder is bladder neck closure associated with chronic suprapubic catheter management. In a retrospective review of 35 patients undergoing this intervention for a variety of conditions (SCI, 71%; MS, 23%; CVA, 9%) the majority of patients had adequate response to therapy. Only 2 patients were incontinent at follow-up. Overall complications were experienced by 17% of patients (Colli and Lloyd, 2011). In another assessment of bladder neck closure and suprapubic tube placement, 29 patients were assessed for the efficacy of this intervention (MS, 48%; SCI, 28%; myelodysplasia, 17%). Bladder neck closure was performed via a retropubic approach in most patients at the time of suprapubic tube placement. Eight of 29 patients had persistent incontinence, 2 with peristomal leakage and 6 with urethral leakage. Catheter complications were associated with 7 of the 8 urinary leaks. Perineal bladder neck closure was associated with much higher fistula rates than retropubic approaches. In addition, poor catheter management also resulted in worse success rates (Ginger et al., 2010). Stein et al. (2005) reported on 24 patients undergoing Mainz pouch diversion. Urinary diversion was associated with stability of the upper tracts and daytime continence, but with some nocturnal incontinence per stoma. Comparing this group with a separate group of patients undergoing bladder augmentation with suburethral fascial sling, all patients in the augmentation group had stability of the upper tracts, and 8 of 10 were continent. Both alternatives were considered adequate for neurogenic voiding dysfunction. Ileovesicostomy also is an option for the management of the neurogenic bladder. In a report of 15 individuals undergoing ileovesicostomy (7 open and 8 robotic), surgical robotic operative times were substantially longer than with open cases; however, there were trends toward less blood loss and shorter hospital stays in the robotic group. With both procedures, there was an improvement in urinary continence from baseline and a trend toward decreased UTI. Overall costs were substantially greater with the robotic versus the open group despite differentials in length of stay. This further underscores the need for further larger studies to assess the possible role of advanced minimally invasive technology for this condition (Vanni and Stoffel, 2011).

Overactive Bladder

W. Stuart Reynolds MD, MPH, Joshua A. Cohn MD

Terminology and Definitions

The International Continence Society (ICS) defined overactive bladder (OAB) syndrome as “**urinary urgency, usually accompanied by frequency and nocturia, with or without urgency urinary incontinence (UUI), in the absence of urinary tract infection (UTI) or other obvious pathology**” (Abrams et al., 2002; Haylen et al., 2010). Therefore OAB syndrome is a syndrome composed of one or more component symptoms of dysfunctional bladder storage associated with a too-frequent or exceptionally strong desire to urinate.

Specifically, the bladder storage symptoms that make up OAB syndrome consist of “increased daytime urinary frequency,” “nocturia,” “urgency,” and “urgency (urinary) incontinence” (Haylen et al., 2010; Table 117.1). The term “urge (urinary) incontinence” was revised to “urgency (urinary) incontinence” for consistency across terms and to better align the language with an undesirable sensation (Abrams et al., 2009).

TABLE 117.1

Standardized Terminology and Definitions to Describe Lower Urinary Tract Dysfunction Related to Overactive Bladder

TERMINOLOGY	DEFINITION	REFERENCE
Overactive bladder syndrome	Urinary urgency, usually accompanied by frequency and nocturia, with or without urgency urinary incontinence, in the absence of urinary tract infection (UTI) or other obvious pathology	Haylen et al., 2010
Increased daytime urinary frequency	Complaint by the patient who considers that he/she voids too often by day[a] (seven voids upper limit of normal[b])	Abrams et al., 2002; Haylen et al., 2010
Nocturia	Complaint of interruption of sleep one or more times because of the need to micturate. Each void is preceded and followed by sleep.	Haylen et al., 2010
Urgency	Complaint of a sudden, compelling desire to void that is difficult to defer	Haylen et al., 2010
Urgency (urinary) incontinence	Complaint of involuntary loss of urine associated with urgency	Haylen et al., 2010

[a] Abrams et al., 2002.

[b] Haylen et al., 2010.

All component symptoms of OAB have been associated with diminished health-related quality of life, with the strongest negative association found for urgency and UUI (Milsom et al., 2012). Bother from daytime urinary frequency is greater in individuals voiding every 2 hours or more frequently, which more or less corresponds to eight or more daytime voids (Lukacz et al., 2009). However, subjective bother for a given number of daytime voids can be variable and significant, even when the number of daytime voids is fewer than eight (FitzGerald et al., 2002). Bother from nocturia is correlated with waking two or more times to void, with more significant bother associated with three or more episodes (Tikkinen et al., 2010). **Nocturia in the absence of other bladder storage symptoms may be related to medical conditions resulting in increased nocturnal urine output or conditions resulting in poor sleep quality rather than lower urinary tract (LUT) dysfunction** (Cornu et al., 2012; Weiss et al., 2011).

The introduction of standardized definitions by the International Continence Society addressed a confusing situation that for many years hampered research and management. The English-speaking world had adopted Patrick Bates's term *unstable bladder* to describe involuntary detrusor contractions seen during urodynamic studies as the bladder was filled, whereas the Scandinavians used the term *detrusor hyperreflexia*. To resolve the discrepancy, the International Continence Society designated the term *unstable bladder* to be applied where there was no obvious cause for the contractions and *detrusor hyperreflexia* for patients whose involuntary contractions were caused neurologically (Bates et al., 1980a,b). Nonetheless, the use of different terms in neurogenic and non-neurogenic patient groups became increasingly difficult. “Overactive Bladder” was the title of a consensus conference, and a formal definition was proposed in 1999 (Abrams and Wein, 1999), culminating in the unified ICS definition that is still used (Abrams et al., 2002). For women, another terminology document, jointly drafted by the International Urogynecology Association and the ICS, was published more recently, with definitions that largely mirror the 2002 ICS document (Haylen et al., 2010).

The syndrome of OAB is based on symptoms; in contrast, detrusor overactivity (DO) is a urodynamic observation, characterized by involuntary detrusor contractions during the filling phase, which may be spontaneous or provoked (Abrams et al., 2002). OAB and DO are thus not interchangeable terms, signified by the recognition that OAB patients undergoing urodynamic testing may not have DO (Al-Ghazo et al., 2011). Conversely DO observed during urodynamics may not be associated with any sensation or may be a consequence of instrumentation rather than reflective of physiology outside of invasive testing.

Mixed Symptoms Incorporating Urinary Urgency

OAB can coexist with stress urinary incontinence (SUI). **Mixed urinary incontinence (MUI) is the "complaint of involuntary loss of urine associated with urgency and also with effort or physical exertion or on sneezing or coughing"** (Haylen et al., 2010). Thus in MUI, SUI and UUI ("OAB wet") are present in the same person. A person with SUI and "OAB dry" does not have MUI; no suitable phrase has yet been standardized for this situation, so such a patient's mixed symptoms should be categorized descriptively. For example, it may be necessary to state that the patient experiences SUI and urgency but does not have UUI.

The coexistence of urinary and anal incontinence can be referred to as "mixed incontinence," and it should not be confused with MUI. Fig. 117.1 describes the relationships among SUI, MUI, and OAB. In general, MUI is associated with more severe levels of leakage, although the relative contributions of the two types of incontinence can be difficult for the patient to quantify, particularly if there is also an element of **insensible urinary incontinence (UI; defined as "complaint of urinary incontinence where the [patient] has been unaware of how it occurred"**) (Haylen et al., 2010).

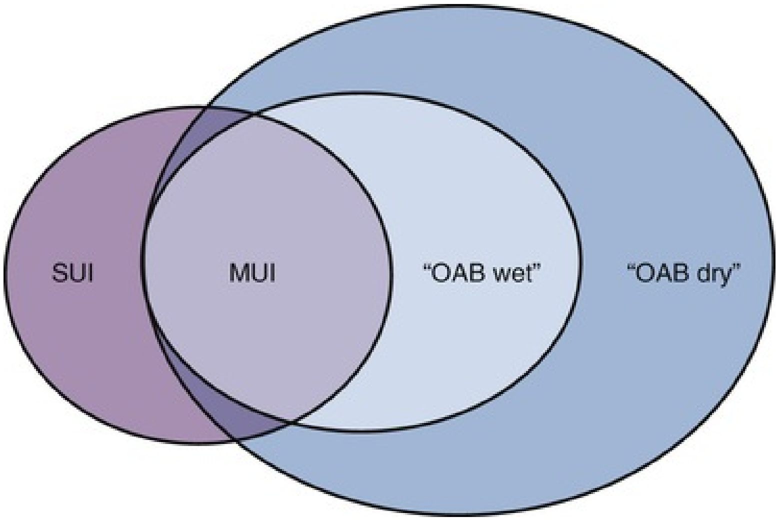

FIG. 117.1 Incontinence may be stress urinary incontinence (SUI), mixed urinary incontinence (MUI), or urgency urinary incontinence ("overactive bladder [OAB] wet"), especially in women. SUI can coexist with "OAB dry," giving rise to mixed symptoms of stress incontinence and urgency.

Distinguishing Overactive Bladder From Bladder Pain Syndrome

Older standardizations defined urgency as a strong desire to void accompanied by the fear of leakage or the fear of pain (Abrams et al., 1988). **However, pain is not typically a component of OAB syndrome but is a required component of bladder pain syndrome (BPS), defined as "the complaint of suprapubic pain related to bladder filling, accompanied by other symptoms such as increased daytime and night-time frequency in the absence of proven urinary infection or other obvious pathology"** (Abrams et al., 2002). Therefore it has been argued that the two conditions are separate entities with symptomatic overlap from urgency and day and nighttime frequency. The entities are distinguished by primary fear of incontinence in OAB and primary fear of pain in bladder pain syndrome (Abrams et al., 2005; Hanno et al., 2008; Fig. 117.2).

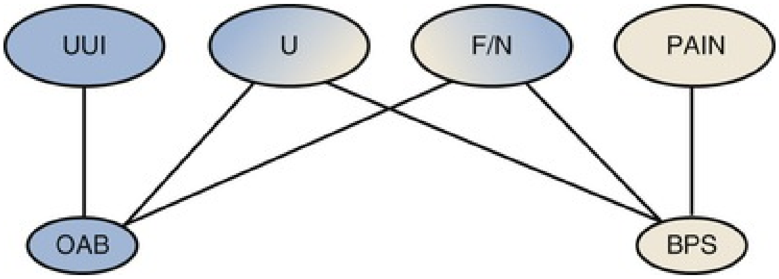

FIG. 117.2 Overactive bladder (OAB) and bladder pain syndrome (BPS) give rise to urgency (U), frequency (F), and nocturia (N); pain, but not urgency urinary incontinence (UUI), is seen in BPS.

The relationship between urgency and filling sensation may be different in OAB and BPS (Fig. 117.3). **Differences that help to distinguish BPS include the painful nature of symptoms, the steady increase in pain with filling, the more consistent voided volumes compared with OAB, and the ability to defer voiding** (albeit at the cost of greater pain). In BPS, suprapubic pain is typical and additional perineal (urethral/vaginal/penile) discomfort and/or pain can also occur (FitzGerald et al., 2005); in OAB, urgency is typically felt in the perineum/base of penis or vagina/urethra.

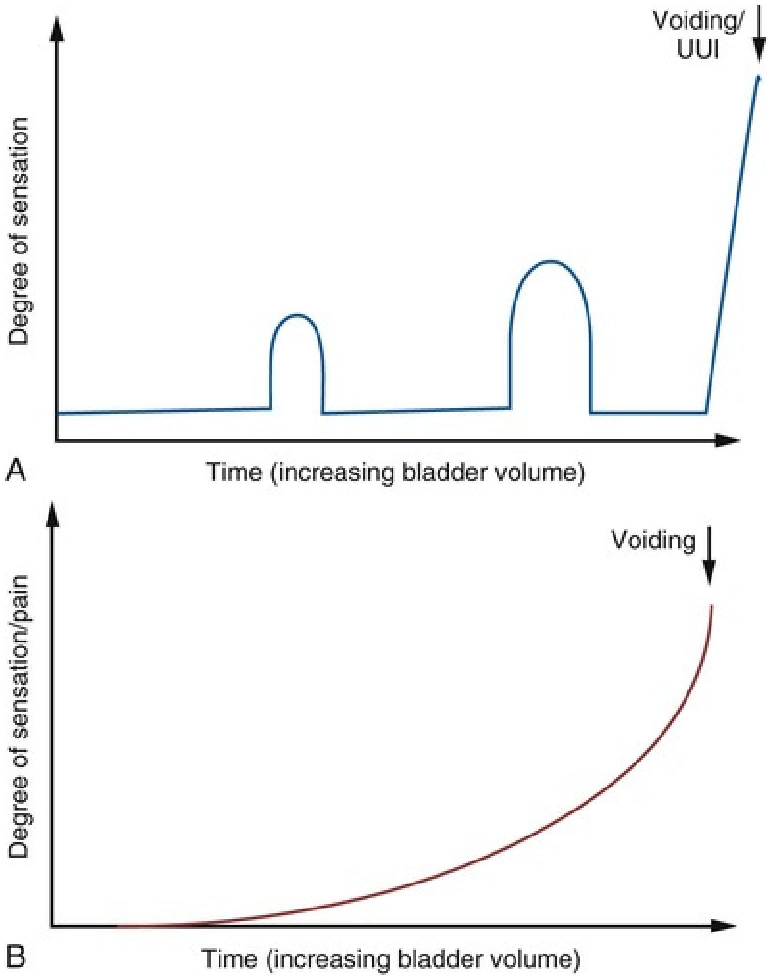

FIG. 117.3 The differences in the development of bladder sensation in overactive bladder (OAB) and bladder pain syndrome (BPS). (A) In OAB, phasic increases in urgency arise and recede as filling progresses, until severe urgency compels the patient to void or an urgency urinary incontinence (UUI) episode sets in. (B) In BPS, pain increases throughout filling, accelerating as filling progresses.

However, it is likely that, in many patients, OAB and bladder pain syndrome are variable presentations of overlapping pathophysiology, possibly rooted in common alterations in afferent nerve sensitivity and/or central sensitization and somatization (Kowalik et al., 2018; Lai et al., 2015, 2016; Reynolds et al., 2017a,b).

Key Points: Overactive Bladder Terminology

- The current definition of OAB is urinary urgency usually accompanied by frequency and nocturia, with or without UUI, in the absence of UTI or other obvious pathology.
- OAB is a symptomatic diagnosis and is distinct from DO, which is a urodynamic observation.
- Urgency is an abnormal sensation defined as the complaint of a sudden compelling desire to void that is difficult to defer.
- Mixed urinary incontinence is the complaint of involuntary leakage associated with urgency and with exertion, effort, sneezing, or coughing.
- “Fear of leakage” and “fear of pain” may distinguish urgency in OAB from BPS; however, the cause of both conditions may be related to different symptomatic manifestations of central sensitization.

Epidemiology and Economics

Prevalence of Overactive Bladder and Related Lower Urinary Tract Symptoms

Several epidemiologic studies provide data on the prevalence of OAB, primarily in the United States (Table 117.2). As is the case with many epidemiologic studies, variations in case definitions and sample populations limit direct comparisons. The overall prevalence of OAB in men and women is variably reported as between 11.8% and 28.7% and UUI 1.5% to as high as 17.3% (Coyne et al., 2009, 2013a; Dooley et al., 2008; Irwin et al., 2006; Kupelian et al., 2006; Stewart et al., 2003), underscoring the tremendous burden of OAB symptoms across ethnically and socioeconomically diverse populations in the United States and Europe.

TABLE 117.2

Studies Examining Prevalence Data for Overactive Bladder

STUDY NAME	POPULATION	METHOD(S), TIMING	DEFINITION OF OAB	PREVALENCE(S)
NOBLE (Stewart et al., 2003)	US population[a], age ≥18 years (n = 5204)	CATI	≥4 episodes of urgency in preceding 4 weeks and ≥8 voids per day or use of bladder coping mechanisms	OAB, 16.5% with UUI, 6.1%
EpiLUTS (Coyne et al., 2009)	Multinational participants, age ≥40 years (n = 30,000)	Internet survey	Urgency at least “sometimes” and/or UUI	OAB, 28.7% with UUI, 17.3%
OAB-POLL (Coyne et al., 2013a)	US participants[a], age 18–70 years (n = 10,000)	Internet survey	Urgency at least “sometimes” and/or UUI	OAB, 23.3% with UUI, 12.6%
NHANES (Dooley et al.,	US population, women[a], age ≥21 years (n = 4229)	Interview	Any incontinence in past 12 months	UUI, 7.9% with MUI, 17%

2008)				
BACH (Kupelian et al., 2006)	Boston, MA[a], age 30–79 years (n = 5506)	Interview	American Urological Association symptom index ≥8	LUTS, 18.7%
EPIC (Irwin et al., 2006)	Multinational, age ≥18 years (n = 19,165)	CATI	ICS definitions	OAB, 11.8% with UUI, 1.5%
Milsom (Milsom et al., 2001)	Multinational, age ≥40 years (n = 16,776)	Interview	Any symptom of OAB	Any OAB symptoms, 16.6%

[a] Selective sampling applied to allow generalization to the US population

BACH, Boston Area Community Health Survey; *CATI,* computer-assisted telephone interviewing; *EpiLUTS,* epidemiology of lower urinary tract symptoms; *ICS,* International Continence Society; *LUTS,* lower urinary tract symptoms; *MUI,* mixed urinary incontinence; *NHANES,* National Health and Nutrition Examination Survey; *NOBLE,* National Overactive Bladder Evaluation; *OAB,* overactive bladder; *OAB-POLL,* impact of overactive bladder on physical and occupational limitations; *UUI,* urgency urinary incontinence.

OAB is common in men and women but tends to disparately affect women. **Most epidemiologic studies report a prevalence of OAB in women of approximately 1.5 to 2 times that of men and rates of UUI of 2 to 3 times those in men.** Although in the National Overactive Bladder Evaluation Study (NOBLE), the incidence of OAB was similar at 16.9% in women and 16.0% in men; 7.6% of women reported UUI versus just 2.6% of men (Stewart et al., 2003). The multinational Epidemiology of Lower Urinary Tract Symptoms (EpiLUTS) reported a prevalence of urgency “at least sometimes” among women with or without associated incontinence of 35.7% versus 22.4% in men and rates UUI of 24.4% in women versus 9.3% in men (Coyne et al., 2009). These findings were echoed in the Overactive Bladder on Physical and Occupational Limitations (OAB-POLL) US-based study, which reported OAB prevalence in women to be approximately double that in men (30.0% vs. 16.4%) (Coyne et al., 2013a).

The prevalence of symptoms of OAB increases with aging, appearing to increase in women in their 40s and men in their 50s and 60s. In the five-country EPIC study, the prevalence of storage of lower urinary tract symptoms (LUTS) was 17.9% and 26.0%, 25.0% and 32.0%, and 43.6% and 46.5% among men and women aged 39 years or younger, 40 to 59 years, and 60 years or older, respectively (Irwin et al., 2006). In NOBLE, aging was associated with a steady increase in OAB in women, whereas OAB in men increased from 8.5% before age 45 years to 21.8% in men more than 55 years of age (Stewart et al., 2003). The prevalence of UUI increased from 2.0% to 19% in women, rising predominantly after age 44 years and from 0.3% to 9% in men with the most dramatic increases observed beyond age 64 years. To this end, beyond age 75 years, 41.9% of men and 31.3% of women in six European countries reported one or more symptoms of OAB versus approximately 10% or less for both sexes before age 55 years (Milsom et al., 2001).

The prevalence of OAB also varies by race/ethnicity for men and women across several studies. The EpiLUTS study reported a prevalence of OAB of 33.3% in African-American men, 28.0% in Hispanic men, 27.0% in Asian men, and 26.3% in white men, and 45.9% of African-American, 43.4% of white, 42.0% of Hispanic, and 26.6% of Asian women (Coyne et al., 2012). The results of OAB-POLL differed slightly despite similar methods but similarly reported slightly higher rates of OAB in African-American men and women than in other ethnic groups (Coyne et al., 2013a). Accordingly, the National Health and Nutrition Examination Survey reported the highest prevalence of UUI in African-American women (11.0%) relative to white and Mexican-American women (7.5% and 7.5%, respectively) (Dooley et al., 2008).

Incidence and Progression of Overactive Bladder

OAB seems to be a dynamic condition, with symptoms waxing and waning over time. Longitudinal study data on the natural history of OAB are limited, but incident new OAB appears to be around 3% to 8% per year in women (Heidler et al., 2011; Irwin et al., 2010; Wennberg et al., 2009). Symptom progression, in terms of developing UUI with a prior history of OAB without UI, is approximately 1% per year, whereas remission of OAB is approximately 6% per year (Heidler et al., 2011).

Health Burden of Overactive Bladder

It is well recognized that OAB causes significant impairment to overall quality of life because it interferes with daily activities as well as contributes to disturbed sleep, decreased self-esteem, decreased sexuality, and feelings of overall declining health. The presence of UUI appears to add an additional degree of burden beyond OAB without UI. For men and women, individuals with OAB are significantly less likely to report moderate and vigorous physical activity in their leisure time (Coyne et al., 2013b).

Almost uniformly men and women with OAB report significantly increased impairment in all aspects of occupation compared with those without OAB, including factors such as work time missed and impairment while working resulting from urinary symptoms. Unemployment is higher for those with OAB than without (men: 43.6% vs. 24.2%, $P < 0.0001$; women: 54.1% vs. 41.4%, $P < 0.0001$) (Coyne et al., 2013b). In addition, individuals with OAB have 2.2 more missed workdays because of medically related absenteeism (RR 1.2, $P < 0.01$) and 3.4 more because of disability (RR 1.7, $P < 0.01$) than those without OAB (Wu et al., 2005).

Despite its commonness, relatively few individuals who have OAB seek care, and even fewer receive care. In fact, individuals with symptoms of OAB often delay seeking treatment or even discussing their symptoms with health care providers (Dmochowski and Newman, 2007). For those who had never discussed OAB symptoms, 84% did not think the problem was important enough, 71% were not asked about OAB by a health care provider, and 69% thought OAB symptoms were just something with which to cope. Even among those who had discussed their symptoms with a provider, 64% thought OAB was something they had to live with and 32% were not aware that anything could be done about it. Overall, only 44% of women surveyed reported being asked about OAB symptoms by their provider.

Fewer than 6% of the population with symptoms of OAB report taking a medication for their symptoms (Hall et al., 2009), the reasons for which are multifactorial. Although individual clinical trials support pharmacotherapy as generally efficacious, in aggregate, the mainstay of pharmacotherapy (i.e., anticholinergic medications) are only modestly superior to placebo (Reynolds et al., 2015; Shamliyan et al., 2012). As such, persistence or compliance with pharmacotherapy is limited. Medical claims and prescription data suggest that 92% of patients with OAB fail initial treatment with anticholinergic medication within 2 years. Most discontinue therapy within the first 6 months after initial prescription, and half do not even refill their initial prescription (Chancellor et al., 2013; Sexton et al., 2011). Primary reasons for discontinuing OAB medications include unmet treatment expectations (46%), side effects (21%), and cost (17%) (Benner et al., 2010).

The costs of OAB therapy extend well beyond those associated with pharmacotherapy. Information on US health care resource use for OAB is relatively scarce. However, it is estimated that, in 2009, US women made 8.1 million ambulatory visits (i.e., 1.6% of all ambulatory visits) associated with anticholinergic OAB medications, representing an annual rate of 68 visits per 1000 women (Ju et al., 2014). From a patient's perspective, the brunt of costs associated with OAB tends to be for routine care, such as incontinence pads, diapers, and laundry, generally reflecting the burden of UI (Subak et al., 2007). However, from a societal perspective, estimates suggest the total costs of OAB in the United States, including direct costs (i.e., medical and nonmedical) and indirect costs (i.e., lost productivity), approached $65.9 billion in 2007, with projected increases to $76.2 billion and $82.6 billion in 2015 and 2020, respectively (Ganz et al., 2010). Estimates of per capita costs are similar between men and women, although direct nonmedical costs were generally higher for women than men, likely reflecting greater UI.

Pathophysiology and Etiology

The pathophysiology of OAB appears multi-factorial and multi-layered across all levels of neural control. Historically, detrusor overactivity (the urodynamic finding of uninhibited detrusor contraction during filling cystometry, DO) (Abrams et al., 2002) was considered the *sine qua non* of OAB. However, DO is no longer considered the defining functional aspect of OAB; less emphasis is placed on this urodynamic finding, in part because of the lack of clinical utility, but also because of more broad acceptance of the definition of OAB based on the symptom of urinary urgency. Indeed, only about half of all patients with DO experience urgency (Wyndaele et al., 2004), whereas among patients with urgency 44% to 69% exhibit DO during cystometric studies (Hashim and Abrams, 2006).

Because the basis of the condition relies on a subjective symptom of urgency, basic science research into OAB has to use indirect or surrogate markers. Thus there is no animal model of OAB, because reporting of subjective symptoms in animals is not possible (Parsons and Drake, 2011). Accordingly, research focus has particularly concentrated on three key aspects: sensory activity, motor control, and reflexes of the LUT.

- Understanding abnormalities of **sensory nerve (afferent) signaling** is appropriate because it is presumed that urgency sensation largely derives from afferent input. The processes involved are signal transduction, afferent traffic, gating, sensitization, and conscious perception. The role of urothelium and the suburothelial layers of the bladder are now considered substantial contributors to the signal transduction and the afferent traffic through the release of mediators (Birder and Andersson, 2013), cellular interactions (Birder et al., 2010), and release of cytokines and growth factors (Andersson and McCloskey, 2014). Sensitization of bladder nerves by inflammation in the gut innervation has been demonstrated experimentally (Malykhina et al., 2012). Conscious perception is not well understood, but functional brain imaging has highlighted centers in the central nervous system (CNS) that could yield valuable information in the future (Arya et al., 2017; Komesu et al., 2011).

- **Contractile (motor) function** comprises the motility of the detrusor muscle and relevant drivers—for example efferent nerves, interstitial cells, and locally released mediators. Increasingly the focus has been to evaluate how these aspects summate in the contractility of the whole bladder, which is what determines the urodynamic observations. The whole organ can manifest areas of localized micromotions adjacent to quiescent areas in a constantly changing play of activity (Fig. 117.4). Thus full understanding of intravesical pressure will not be achieved until properties of the overall motile and nonmotile areas can be explained.

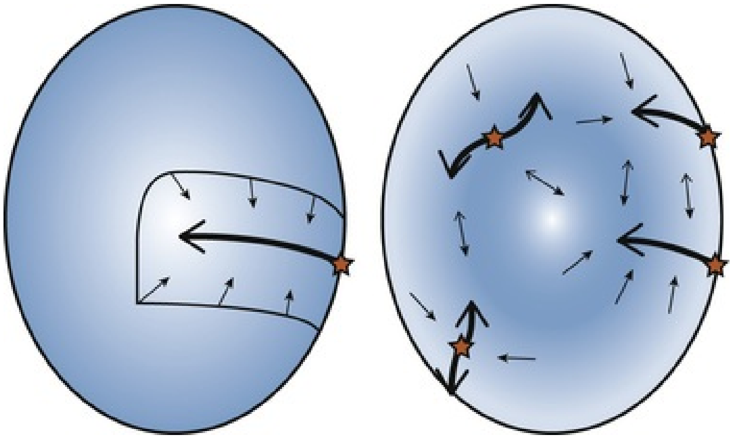

FIG. 117.4 *Left,* Schematic representation of a whole bladder during urinary storage illustrating a localized “micromotion” contraction, starting from an initiation point *(star)*, and spreading to a limited part of the bladder wall. Such activity is characteristic of the normal isolated bladder in all species tested (including human), and it is associated with only small fluctuations in bladder pressure (Drake et al., 2003a, 2003b), presumably because the noncontracting part of the bladder stays relaxed. In the overactive bladder *(right)*, multifocal trigger points lead to continuous activity; this enhances the effect on bladder pressure (as the bulk of the bladder is active) and stimulates afferents by the extensive distorting movements.

- **The sensory information ascending in afferents is integrated at several levels in the CNS** (Drake et al., 2010), where it converges with information from other relevant structures (Fig. 117.5). The integration of this information underpins the coordinated motor behavior of LUT reflexes. In the sacral spinal cord, there is some integration enabling reflex voiding, which is relevant in neonates and in neurologic disease. **The main regulatory region is at the level of the midbrain and brainstem,** where the periaqueductal gray and pontine micturition center integrate the key elements of vegetative function, including the voiding reflex. **At the higher levels of the CNS, more sophisticated aspects are integrated, for example consciousness (LUT sensations, as opposed to subconscious sensory information), awareness of environmental suitability, and voluntary initiation.** There is likely some basic integration in the periphery as well, where interactions may occur between urothelium, interstitial cells, and detrusor muscle (Drake, 2007).

FIG. 117.5 Central nervous system circuitry controls the lower urinary tract (LUT) at multiple levels. Sensory information in afferent is affected by peripheral factors, such as mediators and urothelium. It is carried centrally with some input to the sacral cord, which is important for voiding in infants, and it ascends to the midbrain where it inputs to the pontine micturition center (PMC). At this level there is widespread integration of information from vegetative organs, which is crucial for homeostasis. Sensory information is relayed on to the forebrain, where conscious awareness (sensation) is mediated. The forebrain also mediates voluntary control, including the active decision not to pass urine (storage) or to initiate voiding in the right circumstances. Descending forebrain inputs to the PMC allow the switching from storage to voiding phase, with the synergic regulation of the sacral nuclei responsible for bladder contraction and outlet relaxation. There is also possible integration of sensory information in the periphery, contributing to the generation of bladder motility.

The development of functional brain imaging technology allows estimation of gross activity in specific brain areas and has been used to study bladder filling in normal and symptomatic individuals (Griffiths, 2011). Intriguing insights into contributions from various parts of the cerebral cortex, such as the insula and the prefrontal cortex, have resulted. Alterations in the regional brain activity of symptomatic individuals with OAB have been reported (Arya et al., 2017; Griffiths et al., 2007; Komesu et al., 2011). Early research demonstrating alterations in brain activity in response to sacral nerve stimulation lend further insight into the neural mechanisms of OAB and response to therapy (Gill et al., 2017; Weissbart et al., 2018).

Afferent Mechanisms in Overactive Bladder

In theory, **increased sensory activity may give rise to increased sensation, and hence OAB.** Thus the properties of the bladder afferents and factors that influence them are highly relevant in OAB. **The afferent nerve endings are widely distributed in the bladder wall and are particularly dense in the connective tissue beneath the urothelium.** Afferent nerves innervating the bladder are predominantly small-caliber, myelinated Aδ fibers and are primarily responsible for sensing bladder volume and the contractile state of the detrusor (Birder et al., 2010). These mechanosensitive nerves consist of a combination of low-threshold and high-threshold fibers that are responsive to changes in intravesical pressure and bladder volumes, respectively. With their cell bodies located in the dorsal root ganglia at the S2-S4 and T11-L2 spinal segments, these Aδ fibers are important for normal physiologic filling as they continually gauge the degree of bladder wall distention and convey sensations of bladder fullness to the spinal cord (Kanai, 2011; Kanai and Andersson, 2010). Projections from Aδ fibers synapse with spinal neurons that project to the higher brain centers.

Large-caliber, unmyelinated C fibers are also present and usually respond only to high-intensity activation (such as extreme distention, cold, heat, or chemical irritation) and are thus termed “silent,” as they do not participate in normal physiologic bladder function (Birder et al., 2010; Chapple, 2014). However, in animal models of pathological bladder states such as OAB, these “silent” C fibers can become spontaneously active and hypersensitive to low-intensity input (Häbler et al., 1990; Yoshimura and de Groat, 1999), and these changes are mediated by second-order neurons in the spinal cord (Mazières et al., 1998; Xiao et al., 2014).

Afferent nerves travel through the hypogastric and pelvic nerves along with sympathetic and parasympathetic efferent nerves, respectively. Efferent nerve activity during bladder storage includes direct and indirect stimulation by the sympathetic and parasympathetic systems, which are pathways that have been targeted with common OAB medications (i.e., anticholinergic antimuscarinics and β_3 agonists).

Although several potential mechanisms may contribute, the pathophysiology of OAB can be broadly categorized into mechanisms resulting in abnormally increased afferent signals from the bladder or decreased capacity to modulate afferent signals in the CNS (Chapple, 2014).

Mechanisms of Increased Afferent Activity

There are two predominant hypotheses of increased afferent activity, which may give rise to characteristic symptoms of OAB and to the phenomenon of uninhibited detrusor contractions and DO: the urothelium-based hypothesis and the myogenic hypothesis. However, additional mechanisms may play a role.

In the urothelium-based hypothesis, the urothelium actively responds to local mechanical, osmotic, inflammatory, and chemical stimuli with alterations in expression and/or sensitivity of cell membrane receptors and channels and with release of chemical mediators that act on adjacent afferent neurons, effectively transducing stimulating signals to afferent nerves (Birder et al., 2010; Keay et al., 2014). Urothelial cells exhibit receptor activity for a variety of neurotransmitters, including bradykinin, neurotrophins, purines (P2X and P2Y), norepinephrine (NE) (α and β), acetylcholine (ACh) (nicotinic and muscarinic), epithelial Na^+ channels (ENaC), and a number of transient receptor potential (TRP) channels. These cells can also release signaling molecules that have excitatory and/or inhibitory actions on afferent nerves, including ATP, prostaglandins (PG), nerve growth factor (NGF), ACh, and nitric oxide (NO). It is postulated that in OAB, intrinsic aberrations in homeostatic processes at the level of the urothelium/suburothelium, perhaps in response to unidentified local stimuli, trigger afferent nerve signaling generally in excess of normal levels. This increased afferent activity then augments the afferent stimulation produced by bladder fullness to produce urinary urgency and activate the micturition reflex.

The myogenic hypothesis suggests that overactive detrusor contractions result from a combination of an increased likelihood of spontaneous excitation within the smooth muscle of the bladder and enhanced propagation of this activity to affect an excessive proportion of the bladder wall (Brading, 1997; Brading and Turner, 1994). Patchy denervation is a common observation in DO, regardless of cause (Charlton et al., 1999; Drake et al., 2000; German et al., 1995; Mills et al., 2000). A smooth muscle cell deprived of its innervation shows an upregulation of surface membrane receptors and may have altered membrane potential, which increases the likelihood of spontaneous contraction in that cell. DO is also associated with structural changes (Elbadawi et al., 1993; Haferkamp et al., 2003a,b), which could facilitate the excessive spread of spontaneous contractions throughout a wider proportion of the bladder than normal. Although the observations in different models of DO and from clinical specimens do not uniformly describe these features, understanding of altered smooth muscle behavior remains a relevant factor for understanding DO.

Furthermore, the myogenic hypothesis suggests that a range of triggers can generate localized detrusor contractions, which can spread in the bladder wall through various routes of propagation. Coolsaet et al. (1993) described localized contractions **(“micromotions”)** in pigs, and these contractions were postulated as a basis for urinary urgency. They have been widely reported in normal animals and humans. Importantly, such micromotions are exaggerated in models of DO and in human OAB (Drake et al., 2003a,b, 2005; Van Os-Bossagh et al., 2001). **Normal small distortions caused by micromotions may be detected by afferents, therefore generating the sensation of bladder filling without change in detrusor pressure (see Fig. 117.4). In OAB, the distortions may be excessive as a result of exaggerated**

micromotions. They will be associated with urgency and possibly urodynamic DO if the movements become coordinated across a substantial proportion of the bladder (Drake et al., 2001).

Other Mechanisms of Increased Afferent Signaling.

In addition to the above mechanisms for increased afferent signaling arising from the bladder (i.e., the urothelium and myogenic hypotheses), additional mechanisms may result in increased bladder afferent signaling that may arise independent of the bladder. **Specifically, bladder overactivity may result from stimulating signals that arise separately from the bladder but act on the bladder through common afferent pathways** (Chapple, 2014; Kanai, 2011; Ustinova et al., 2010). Overlapping neural pathways that converge in the CNS at the level of the dorsal root ganglia, the spinal cord, or the brain underscore pelvic organ cross-talk (Arendt-Nielsen and Yarnitsky, 2009; Malykhina, 2007; Ustinova et al., 2010). Visceral organ cross-talk involving the bladder is best understood relative to the bowel, which shares sensory innervation in regions of the thoracic and sacral spinal cord with the bladder (Giamberardino et al., 2010). Convergent neural mechanisms of the bladder and the bowel explain the reproducible interactions demonstrated in experimental models (Brumovsky and Gebhart, 2010; Malykhina et al., 2012; Ustinova et al., 2010). For instance, in animal studies, rectal stimulation either through distention (Minagawa et al., 2013; Wyndaele et al., 2013) or inflammation (Malykhina et al., 2006) precipitates detrusor inhibition and/or overactivity that is mediated by activation of convergent bladder and bowel C-fiber afferent nerves in the spinal cord (Minagawa et al., 2013). Similarly, in animal models of pelvic pain or cystitis, colonic stimulation increases pain responses attributed to bladder inflammation (Rudick et al., 2007). Clinical studies that document overlap between bladder and bowel function (Guo et al., 2010; Monga et al., 1997; Wyndaele et al., 2011, 2015) support these experimental findings from animal models. For example, rectal distention results in changes in bladder capacity, bladder sensation, and detrusor overactivity (Burgers et al., 2013; De Wachter and Wyndaele, 2003), while straining to defecate and constipation can impair bladder emptying and increase the severity of voiding and storage symptoms (Alling Møller et al., 2000; Cardozo and Robinson, 2002; Carter and Beer-Gabel, 2012; Coyne et al., 2011; Klingele et al., 2010; Wyndaele et al., 2011, 2015).

Abnormal Handling of Afferent Signals.

In addition to increased afferent activity from the bladder and other sources, an abnormal handling of afferent signals also may play a role in the pathophysiology of OAB. **Even in a nonpathological state, continuous bladder afferent activity during the micturition cycle delivers a myriad of signals conveying pain, mechanosensation, chemical sensitivity, and motor and/or sensory function to the CNS for processing** (Gillespie et al., 2009). Termed “afferent noise,” only a fraction of these signals generate sensations, although most components contribute to reflexes coordinating bladder filling, sphincter function, and voiding. **The CNS is responsible for modulating these signals to suppress unnecessary and/or unconscious bladder sensations and to facilitate afferent signals necessary for homeostasis. If the CNS is unable to modulate these signals appropriately because of disease or dysfunction, then these normally unconscious bladder sensations may be perceived as urgency.**

Neurologic disease is associated with a high prevalence of LUT dysfunction, including OAB, and this is to be anticipated from the fundamental regulatory influence of the innervation on the bladder and its outlet. **Given that most of the time the bladder is storing urine (rather than emptying), it is likely that the CNS exerts continuous inhibitory influence on bladder contractility**, whether through sympathetic inhibition of the detrusor muscle directly through β_3 adrenoceptors, or indirectly by inhibiting parasympathetic ganglia. Thus neurologic disease may affect the continuous inhibition, leading to emergence of OAB symptoms.

Other Pathophysiologic Mechanisms

Additional potential factors appear to contribute to the development of OAB, likely at the level of the bladder, by promoting urothelial and myogenic dysfunction and leading to alterations in nerve mechanisms, including increased afferent activity. Ischemia and reperfusion injury are proposed to cause OAB via hypoxia and oxidative stress pathways, as may be seen in the setting atherosclerosis or arterial obstruction, resulting in damage to epithelial cells, smooth muscle cells, microvasculature, and nerve fibers (Zhao et al., 2016). Evidence of chronic inflammation as measured by increases in cytokines, chemokines, and growth factors isolated from bladder tissue samples, urine, and blood point to upregulation of pro-inflammatory processes in the development of OAB (Kashyap et al., 2018; Kupelian et al., 2012; Tyagi et al., 2014). Recent investigations into urine microbiota demonstrating differences in patients with UUI and OAB suggest that changes in urine microbial composition may contribute to OAB; however, the relation to signaling systems in the bladder-brain axis remains unknown (Pearce et al., 2014, 2015; Thomas-White et al., 2016).

Etiology and Attributable Risk Factors

For most cases of OAB, the cause is unknown and likely multifactorial. Attributable risk factors associated with OAB may affect pathophysiologic mechanisms to initiate or exacerbate the OAB disease process. **Aging is clearly associated with increased LUTS, including OAB;** the wide range of changes in cellular function and the CNS means that increasing OAB with aging is probably multifactorial. As noted, OAB occurs in men and women, although most studies report higher prevalence in women, especially younger women, and higher rates of UUI in women (Coyne et al., 2009). Partial bladder outlet obstruction (BOO) has long been considered an etiologic factor in the generation of DO and OAB, and BOO is a widely used means of generating enhanced nonmicturition contractions as an animal model of DO. However, the relationship between BOO and DO or OAB in humans is not clear cut. Prevalence of OAB in women, in whom BOO is rare, is broadly similar to that in men, in whom BOO is common because of prostate enlargement. Furthermore, DO rarely resolves with prostate surgery. Overall, BOO is probably a relevant factor, but **the influence of BOO may be indirect, perhaps by accelerating some of the changes brought on by aging.** Epidemiologic data on racial/ethnic differences in OAB suggest there may be associated factors, but the underlying details remain unknown.

There are psychological overtones involved in the experience of OAB, and interest in psychological and psychosocial factors associated with OAB is increasing. Many authors have described the associations between psychological conditions and OAB, which further compound the health burden OAB experienced by affected individuals. The most widely studied associations are depression and anxiety (Kinsey et al., 2016); however, OAB also significantly affects self-esteem, sexuality, and relationships. Personal embarrassment and shame are common themes as well. Overall, individuals with concomitant incontinence (OAB and urge-UI) report more psychological burden than those without UI (Vrijens et al., 2015). **Although the strong association between**

psychology and OAB suggests a possible causative effect, the nature of this relationship requires further study (Cortes et al., 2012)**, because it may involve serotonergic mechanisms on the CNS and/or dysregulation of the pituitary-hypothalamic-adrenal axis** (Vrijens et al., 2015). Indeed, stress appears to affect OAB via this route (Smith et al., 2016).

The overlap with other functional syndromes and other health influences indicates the need to recognize wider contributory factors to mechanisms underlying the emergence of OAB and its clinical assessment, particularly in relation to bowel function (Daly and Chapple, 2013; Kaplan et al., 2013), metabolic syndrome (Bunn et al., 2015; Lai et al., 2018), and hormonal status (Robinson et al., 2014).

Key Points: Pathophysiology and Etiology

- Sensory information ascending along afferent pathways are integrated at multiple levels of the CNS, with the main regulatory regions located at the level of the midbrain and brainstem.
- Failure of integration of afferent inputs and sensory inputs at the highest levels of the CNS resulting from disease or dysfunction may lead to perception of normally unconscious symptoms as urgency.
- The urothelium-based and myogenic hypotheses are the two primary bladder-centric theories behind the mechanisms of OAB.
- In the urothelium-based hypothesis, the urothelium actively responds to local mechanical, osmotic, inflammatory, and chemical stimuli, resulting in increased stimulation of afferent nerves.
- The myogenic hypothesis posits that overactive detrusor contractions result from spontaneous excitation within the smooth muscle of the bladder and enhanced propagation of this activity to affect an excessive proportion of the bladder wall.
- The relationship between BOO and OAB is not likely to be a direct causal relationship but rather separate consequences of changes associated with aging.

Clinical Assessment

Initial Evaluation

OAB is a syndrome diagnosed by the presence of characteristic LUTS (Abrams et al., 2002). Empiric treatment can be delivered based upon clinical history and noninvasive testing aimed at characterizing symptoms and ruling out an acute causative process. The American Urological Association/Society of Urodynamics, Female Pelvic Medicine & Urogenital Reconstruction (AUA/SUFU) Guideline for the Diagnosis and Treatment of Overactive Bladder (Non-neurogenic) in Adults maintains **a careful history, physical examination, and urinalysis as the appropriate initial components of evaluation** (Gormley et al., 2012, 2015). The European Association of Urology's Guidelines on the Management of Non-Neurogenic Male Lower Urinary Tract Symptoms (LUTS), including Benign Prostatic Obstruction (BPO) (Gratzke et al., 2015) and Guidelines on Urinary Incontinence (Lucas et al., 2012) concur with these recommendations and strongly encourage the use of validated symptom questionnaires when feasible.

History

The clinical history should establish the diagnosis and assess bother. The following elements should be covered:

- **Presence of and bother from each of the storage LUTS that make up the OAB syndrome (i.e., urgency, urgency incontinence, daytime frequency, and nocturia), other storage disorders (e.g., SUI), and voiding LUTS (e.g., straining, hesitancy, sensation of incomplete emptying) whose presence may indicate BOO. Post-micturition LUTS, dysuria, hematuria, and hematuria should also be assessed.** Symptom assessment questionnaires may facilitate this process but may be of limited utility in many patients because of poor health literacy or a language barrier (Table 117.3; Anger et al., 2012; Moses et al., 2017; Senekjian et al., 2011; Wang et al., 2013).

TABLE 117.3

Description and Readability of Common Lower Urinary Tract Symptoms Assessment Questionnaires

QUESTIONNAIRE	DESCRIPTION	READING GRADE LEVEL (RANGE)	REFERENCE
American Urological Association Symptom Index (AUASI)	7-items, 0–5 scale, assessing voiding and storage components (0–35 total score) and a 0–6 quality of life score	6[a]	Barry et al., 1992
Urogenital Distress Inventory (UDI)	19-item, 4-point bother scale, 3 subscales (storage symptoms, voiding symptoms, stress urinary incontinence) 0–100 summed for 0–300 score	10.5 (7.7–12.0)[b]	Shumaker et al., 1994
Urogenital Distress Inventory-6 (UDI-6)	Reduced 6-item questionnaire from parent survey, scaled to 0–100 score	8.4 (4.8–12.0)[b]	Uebersax et al., 1995
Incontinence Impact Questionnaire (IIQ)	30-item assessment of impact of UDI symptoms	11 (8.5–12.0)[b]	Shumaker et al., 1994
Incontinence Impact Questionnaire-7 (IIQ-7)	Reduced 7-item questionnaire from parent survey, scaled to 0–100 score	11 (9.5–12.0)[b]	Uebersax et al., 1995
Bristol Female Lower Urinary Tract Symptoms (BFLUTS)	33-item assessment of storage and voiding symptoms (12), incontinence (8), quality of life (9), sexual function (4)	7.1 (2.2–12.0)[b]	Jackson et al., 1996
Bristol Female Lower Urinary Tract Symptoms-Short Form (BFLUTS-SF)	12-item reduced questionnaire from parent-form	6.3 (3.2–12.0)[b]	Brookes et al., 2004
Overactive Bladder Questionnaire (OAB-q)	8-item bother scale and 25 quality of life items, 0–6 scale, summed and adjusted to 0–100 score	Not assessed	Coyne et al., 2002
Overactive Bladder Questionnaire Short Form (OAB-q SF)	6-items from OAB-q bother scale and 13 from HRQL scale	Not assessed	Coyne et al., 2015

- **Nature and volume of fluid intake**, recognizing that stimulants (e.g., caffeine) and polydipsia affect LUTS and that patients may adapt their intake to reduce the impact of symptoms.
- **Whether occult neurologic disease could be present**; for example, recent onset of OAB with symptoms of erectile dysfunction or tremor or history of spine surgery or disk disease with or without sensory and/or musculoskeletal symptoms.
- **Obstetric and gynecologic history, previous surgery and/or radiotherapy, bowel symptoms (i.e., constipation, diarrhea, fecal incontinence), and medication history**. The prevalence of fecal incontinence is 7% to 15% in the general population but may be closer to 50% in women with OAB (Bharucha et al., 2015; Lim et al., 2018)**.**
- **Other medical conditions that may directly contribute to LUTS** (e.g., polyuria resulting from poorly controlled diabetes), may be relative contraindications to therapy with antimuscarinics (e.g., poorly controlled closed-angle glaucoma, cognitive impairment, history of urinary retention, and impaired gastric emptying) or β_3 agonists (e.g., poorly controlled hypertension, cardiac arrhythmia), or may be associated with behaviors or medications associated with increased urine output (e.g., obstructive sleep apnea, psychogenic primary polydipsia, lithium-induced diabetes insipidus).

A frequency-volume chart (FVC) (Abrams and Klevmark, 1996) can be informative in all cases but particularly when history suggests that polyuria is responsible for urinary frequency and/or nocturia in isolation or in combination with bladder dysfunction (Cornu et al., 2012). **In OAB the pattern of voided volumes is characteristically erratic. On the FVC, frequency is defined as**

the number of voids recorded during waking hours, including the last void before sleep and the first void after waking and rising in the morning (Abrams et al., 2002)**.** The maximum voided volume on an FVC can be used as a measure of OAB severity, and it has also been used to estimate severity of DO (Miller et al., 2002). In addition, the bladder diary collects objective information on fluid intake and incontinence episodes. A symptom scale has been evaluated for use in conjunction with a bladder diary validated by the International Consultation on Incontinence Questionnaire (ICIQ) group in nonselected populations (Bright et al., 2012, 2014; Table 117.4).

TABLE 117.4

Bladder Sensation Scale Used in the International Consultation on Incontinence Questionnaire Bladder Diary

SCALE	DESCRIPTION
0	If you had no sensation of needing to pass urine, but passed urine for “social reasons,” for example, just before going out or because you are unsure where the next toilet is
1	If you had a normal desire to pass urine and no urgency. Urgency is different from normal bladder feelings and is the sudden compelling desire to pass urine that is difficult to defer, or a sudden feeling that you need to pass urine and if you don't you will have an accident
2	If you had urgency but it passed before you had to visit the toilet
3	If you had urgency and managed to get to the toilet, still with urgency, but did not leak urine

From Bright E, Cotterill N, Drake M, et al.: Developing a validated urinary diary: phase 1. *Neurourol Urodyn* 31(5):625–633, 2012.

The Patient Perception of Intensity of Urgency Scale (PPIUS) is a five-point scale designed to rate the level of urinary urgency for each void during completion of a micturition diary (Cartwright et al., 2011).

1. No urgency: I felt no need to empty my bladder but did so for other reasons.
2. Mild urgency: I could postpone voiding for as long as necessary without fear of wetting myself.
3. Moderate urgency: I could postpone voiding for a short while without fear of wetting myself.
4. Severe urgency: I could not postpone voiding but had to rush to the toilet

to avoid wetting myself.
5. Urgency incontinence: I leaked before arriving at the toilet.

Increased frequency may be a behavioral response to urgency, as patients attempt to reduce the incidence of severe urgency or incontinence, and this can be assessed with additional interpretations of the measures mentioned previously. The total urgency and frequency score (TUFS) (Chapple et al., 2014) is calculated by adding the PPIUS scores of every void by a patient in the patient's voiding diary and dividing this number by the number of days recorded in the diary. The OAB Symptom Composite Score (OAB-SCS) (Zinner et al., 2005) is a similarly derived by summation of Indevus Urgency Severity Scale scores but has not been validated.

Compliance with the fairly cumbersome task of completing an FVC may limit its utility in clinical practice. Use of an electronic diary and smartphone applications can facilitate data collection and analysis (Abrams et al., 2016).

Physical Examination

Focused physical examination should include the abdomen and pelvis, extremities (e.g., edema, tremor), a basic neurologic examination, and general assessment of cognition and frailty (Wagg et al., 2015). Assessment of bladder emptying is necessary. This can be performed by palpation of the lower abdomen in a slim patient but in the urology clinic is more commonly performed with a bladder scanner. The decision to obtain a postvoid residual (PVR) is at the discretion of the clinician but has become routine; with a bladder scanner it can provide important information at little cost or discomfort for the patient (Gormley et al., 2012, 2015; Gratzke et al., 2015).

Laboratory Examination

Urinalysis is mandatory in all patients to exclude urinary tract infection, hematuria, and pyuria. Urine culture should be obtained if infection is suspected based upon the clinical presentation and urinalysis. Assessment of renal function with serum creatinine and urea nitrogen is not routinely indicated but should be reviewed if available.

Advanced Evaluation

Urodynamics, cystoscopy, and diagnostic renal and bladder ultrasound should not be used in the initial workup of the uncomplicated patient (Gormley et al., 2012, 2015). The decision to pursue cystourethroscopy and imaging is based upon the presence of symptoms or urinalysis findings requiring these studies. Although controversy exists over the definition and public health implications of widespread workup of asymptomatic microscopic hematuria (Asymptomatic microscopic hematuria in women, 2017; Davis et al., 2012; Subak and Grady, 2017), the clinician should be bear in mind that patients with OAB and microscopic hematuria are not asymptomatic. To this end, the association between LUTS and LUT pathology such as cancer or stricture should be borne in mind and potentially lower the threshold for cystoscopic evaluation (Hampson et al., 2016; Zhou et al., 2015).

Consensus guidelines recommend urodynamics testing when the presence or absence of altered compliance, DO, or other urodynamic abnormalities will affect the decision to pursue or avoid an invasive, irreversible, or potentially morbid treatment (Abrams et al., 2013; Nambiar et al., 2017; Winters et al., 2012). Treatment based upon urodynamics testing may improve treatment satisfaction (Verghese et al., 2018); however, urodynamics have not been clearly shown to improve outcomes for the index OAB patient (i.e., a woman with low PVR, no significant prolapse, no neurologic disease, and minimal stress urinary incontinence) (Goldman et al., 2018). Urodynamics may be beneficial in patients in whom the presence of BOO is suspected, such as those who have persistent or new-onset OAB symptoms after an outlet procedure.

The primary aim of urodynamic studies is to reproduce the patient's symptoms and to identify additional factors likely to influence management decisions, the likelihood of which is increased by adhering to ICS Good Urodynamic Practices (Schäfer et al., 2002). **The two main urodynamic diagnoses associated with OAB are DO (Fig. 117.6) and early and/or exaggerated filling sensation.** Whether to discontinue antimuscarinic drugs before urodynamic testing can be argued either way; stopping the drugs provides the best chance of observing DO if present, whereas continuing them allows evaluation of the mechanism underlying residual refractory symptoms.

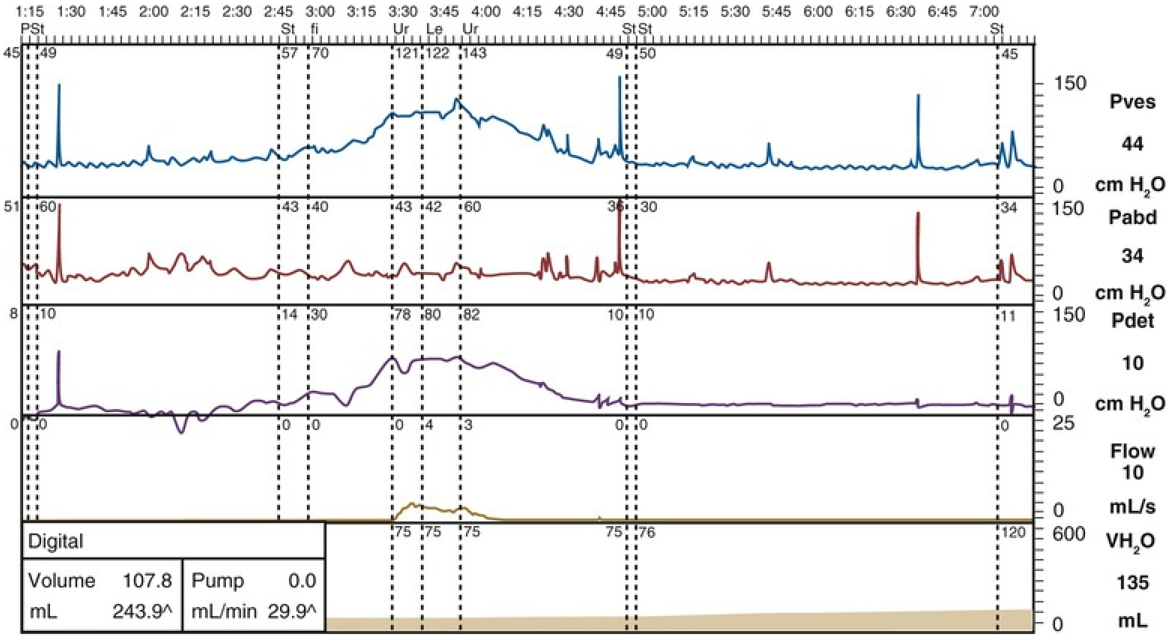

FIG. 117.6 Filling cystometry urodynamic trace showing detrusor overactivity incontinence. *Blue,* Bladder pressure (Pves; *top*). *Red,* Rectal pressure (Pabd). *Purple,* Detrusor pressure (Pdet). *Light brown,* Flow. *Orange*, Filling (VH_2O; *bottom*). The bladder pressure and detrusor pressure rise substantially from baseline, and between 3 minutes 30 seconds and 4 minutes *(top axis)*, there is incontinence seen in the flow trace that is associated with urgency (Ur).

The ICS report describes two types of DO (Abrams et al., 2002):

1. **Phasic DO** is the characteristic pattern seen in most idiopathic DO. It exhibits a characteristic waveform and may or may not lead to incontinence (see Fig. 117.6). It tends to be characterized by contractions of increasing amplitude as the bladder volume increases.
2. **Terminal DO** is a single involuntary detrusor contraction occurring at cystometric capacity, which causes incontinence, often resulting in complete bladder emptying. It is most characteristically seen in the elderly person with “precipitant voiding,” such as in elderly patients who have suffered a cerebrovascular accident. Such patients appear to lose awareness of impending micturition and the ability to inhibit what turns out to be a voiding contraction.

Nonphasic changes in detrusor pressure before micturition should be regarded as changes in bladder compliance rather than as DO. Note that some patients with DO are asymptomatic (i.e., they do not experience OAB). **Any phasic**

detrusor contraction during filling constitutes DO, regardless of amplitude (Abrams et al., 2002). **DO may be absent in many patients with OAB, but its presence is correlated with increased severity of urgency and the presence of incontinence** (Al-Zahrani and Gajewski, 2012, 2016; Chung et al., 2011; Hashim and Abrams, 2006). Accordingly, approximately 60% to 70% of men and 40% to 50% of women with urinary urgency without incontinence ("OAB-dry") will have DO on cystometrogram, whereas nearly all men (>90%) with UI ("OAB-wet") will demonstrate DO. Because of the "misinterpretation" of SUI as urgency leakage, incontinence in women is a less reliable predictor of DO, which may be absent in 30% to 40% of women with reported urgency incontinence (Al-Ghazo et al., 2011; Hashim and Abrams, 2006). Contact of urine with urethral receptors caused by urodynamic stress incontinence (USI) may stimulate urethral receptors, causing an urgency sensation and perhaps a secondary bladder contraction. In some individuals, DO can be elicited by asking the patient to cough; this stress-provoked DO (in which cough results in DO, which causes leakage) must not be confused with USI (in which the cough causes an immediate leak and no DO is seen).

Fig. 117.7 illustrates the relationship between the symptom-based diagnosis of OAB and the urodynamic-based diagnosis of DO. **Where DO is absent the patient will usually report increased bladder sensation, defined as "an early and persistent desire to void"** (Abrams et al., 2002). If DO is not seen during filling, the investigator should attempt to use any provocations that the patient says lead to OAB symptoms, such as the sound of running water or having the patient stand up if possible. Filling rate must be considered carefully; a high filling rate can be used to induce DO. However, a high filling rate may also result in repeated DO that prevents assessment of other urodynamic parameters relevant to the patient's presenting symptoms such as flow rate and detrusor pressure during a volitional void. Fast filling can also mask DO and cause low compliance, particularly in neurogenic DO.

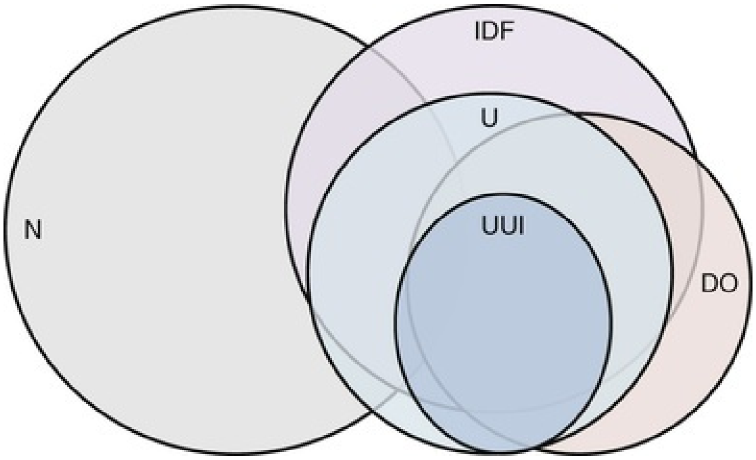

FIG. 117.7 Correlation between the symptom-based diagnosis of overactive bladder (increased daytime frequency [IDF], urgency [U], nocturia [N], and urgency urinary incontinence [UUI]) and the urodynamic diagnosis of detrusor overactivity (DO). The correlation is best for UUI and worst for N.

It is critical to assess for the presence of BOO or inefficient bladder emptying for two reasons. First, **OAB treatment measures that aim to improve bladder reservoir function may impair voiding, perhaps necessitating intermittent self-catheterization.** For example, each 10-mL increase in PVR has been associated with a 27% increased risk of need for catheterization after botulinum toxin injection (Osborn et al., 2015). Second, **increasing severity of BOO is associated with DO** (Oelke et al., 2008; Oh et al., 2011), **suggesting that OAB symptoms may be unlikely to improve if BOO is left untreated. However, treatment of BOO does not necessarily result in improvement in OAB symptoms.** The prevalence of DO may be as high as 60% in men who have undergone prior transurethral resection of the prostate (TURP) (Thomas et al., 2005), despite the fact that they remain unobstructed. **The urodynamic finding that has been most consistently associated with decreased likelihood of resolution of DO or OAB symptoms is terminal DO at diminished capacity** (Antunes et al., 2015; Zhao et al., 2014). Although symptomatic improvement is seen in many men with BOO and DO, it is probably less likely than in men without DO.

Ideally the patient should be seated or standing for filling cystometry, because OAB symptoms are usually experienced when upright. However, where there is severe DO at low volumes, it may be difficult to ascertain if USI is also present. In these patients, a second filling cycle in the supine position generally reduces DO (Al-Hayek et al., 2008), making it easier to detect USI if present.

The urodynamic report should clearly state whether the patients' symptoms were reproduced completely, reproduced in part, or not reproduced to ensure that due caution is exercised in major treatment decisions where there is diagnostic uncertainty. Technical artifacts should be recognized and handled immediately (Hogan et al., 2012; Schäfer et al., 2002). **Ambulatory urodynamics may be considered when conventional cystometry fails to reproduce symptoms. However, DO may be difficult to interpret because it has been found in more than 60% of asymptomatic women undergoing ambulatory urodynamics** (Heslington and Hilton, 1996).

Key Points: Overactive Bladder Clinical Assessment

- The minimum requirements to document symptoms and signs of OAB and to exclude other potential causative disorders are a careful history, physical exam, and urinalysis.
- Clinicians must consider the possibility of malignancy, neurologic disease, systemic disease, and/or an elevated postvoid residual.
- The frequency volume chart is the principal method for objective evaluation of day and nighttime frequency and polyuria.
- Urodynamics, cystoscopy, and diagnostic renal and bladder ultrasound should not be used in the initial workup of the uncomplicated patient.
- Urodynamics testing is indicated when the presence or absence of altered compliance, DO, or other urodynamic abnormalities will affect the decision to pursue or avoid an invasive, irreversible, or potentially morbid treatment.
- Increasing severity of BOO is associated with the presence of DO; however, treatment of obstruction does not ensure OAB symptom resolution.

Management

In general, OAB is a chronic symptom complex that affects quality of life but is not life threatening. Patients should be informed as such and management recommendations made within this context. Patients may elect not to proceed with any intervention whose benefits do not outweigh the financial, physical, or opportunity costs associated with treatment.

First-Line Therapy

First-line therapy for OAB includes behavioral therapies such as bladder training, bladder control strategies, pelvic floor physical therapy, weight loss, and fluid management (Gormley et al., 2012, 2015; Nambiar et al., 2018). Patients in clinical trials receiving placebo therapy experience significant benefits across multiple OAB symptom parameters, including daily incontinence and micturition episodes and mean voided volume (Mangera et al., 2011). The “placebo effect” consistently observed across OAB trials underscores the benefit of non-pharmacologic intervention, often in the form of education, on symptoms.

Fluid reduction can improve OAB symptom scores (Imamura et al., 2015), **albeit at the cost of thirst and other adverse effects of underhydration.** Furthermore, many patients have already implemented fluid avoidance strategies before seeking care, limiting its efficacy as an intervention (Smith et al., 2011). Nevertheless, a decrease in fluid intake by 25% can be expected to meaningfully reduce OAB symptoms and should be encouraged when feasible (Hashim and Abrams, 2008).

Caffeine reduction has not been consistently demonstrated to reduce urinary incontinence but does improve other OAB symptoms such as urgency and frequency (Arya et al., 2000; Bryant et al., 2002; Swithinbank et al., 2005; Tomlinson et al., 1999). Patients should be educated about the impact of caffeine on symptoms and encouraged to assess whether any perceived improvement in symptoms is “worth” the trade-off of giving up or reducing intake of the caffeinated beverages they enjoy.

Weight loss reduces stress urinary incontinence but may significantly reduce episodes of UUI as well. To this end, mean weight loss of 7.8 kg among obese women with incontinence randomized to an intensive weight-loss program was associated with a significantly greater likelihood of meaningful decrease in UUI episodes relative to controls (who experienced mean weight loss of 1.5 kg) (Subak et al., 2009). Patients with severe obesity may benefit from a caring and honest discussion regarding the potential benefits of bariatric surgery, which has been associated with an approximately 7% to 8% reduced risk of urinary incontinence per each 5% reduction in weight (Subak et al., 2015).

Behavioral therapies such as pelvic floor muscle training and bladder training can significantly improve urinary urgency and urgency incontinence episodes among patients committed to treatment at little or no risk of adverse effects. Improvement in the frequency of incontinence episodes is typically 50% to 80%, and as such behavioral treatments are endorsed as first-line treatment by multiple societies (Corcos et al., 2017; Gormley et al., 2012, 2015; Nambiar et al., 2018). Behavioral therapy may be offered concomitantly with medical therapy according to patient preferences and symptoms.

Second-Line Therapy

Options for pharmacologic management of OAB predominantly include antimuscarinic agents as well as β_3 agonists. Pharmacologic management of OAB is covered in detail in another chapter. If recommending antimuscarinic medication, prescribers should educate the patient about potential side effects, including dry mouth, constipation, cognitive effects, visual impairment, and others (Leone Roberti Maggiore et al., 2012). A range of agents and doses are available, and patients should be advised that the idiosyncratic nature of responses means that it may take some adjustment to find an optimum regimen. In general, antimuscarinic agents have been found to increase likelihood of cure over placebo by 20% to 70% but are associated with a high rate of withdrawal because of inefficacy or adverse events (Nambiar et al., 2018). **Extended-release formulations should preferentially be prescribed in favor of short-acting formulations** because of lower rates of dry mouth (Gormley et al., 2012, 2015; Nambiar et al., 2018), and if a patient experiences inadequate symptom control and/or unacceptable adverse drug events with one antimuscarinic medication, then a dose modification or a different antimuscarinic medication may be tried. **The β_3-adrenergic agonist mirabegron has become an established treatment of OAB with decreased risk of dry mouth but otherwise similar rates of adverse events and efficacy relative to antimuscarinic therapy** (Nitti et al., 2013b). In men with voiding LUTS, α_1-

adrenergic antagonists represent first-line drug therapy; however, in men with LUTS suggestive of OAB, inclusion of an antimuscarinic in may be appropriate (Gratzke et al., 2015; Nambiar et al., 2018). The use of **an antimuscarinic in the treatment of a man with BOO and concomitant OAB can ameliorate symptoms and provide a modest improvement in quality of life** (Athanasopoulos et al., 2011). However, the incidence of **acute urinary retention in men receiving antimuscarinics with or without an α_1-adrenergic blocker is up to 3%** (Kaplan et al., 2011). Therefore caution is advised in initiating OAB therapy when PVR is elevated, particularly at volumes exceeding 250 mL (McVary et al., 2011).

In evaluation of response to pharmacologic therapy, **repeat use of the symptom assessment questionnaire is valuable because subjective perceptions and recollections of LUTS can be unreliable.** In patients failing initial pharmacologic treatment, **altered drug dose, a different agent, or combination therapy may achieve sufficient improvement to obviate the need to consider more invasive investigation and treatment.**

Third-Line Therapy

Third-line interventions for OAB primarily include tibial nerve stimulation, sacral nerve stimulation, and intravesical botulinum toxin injection. Each of these treatments, which are reviewed in detail later in this text, may be offered for OAB symptoms refractory to first- and second-line therapy because of either inefficacy or intolerance. Treatment selection, including the decision not to proceed with further therapy, depends on patient preferences, which should be guided by an informative discussion of benefits and drawbacks of each.

Tibial nerve stimulation may result in clinical response in approximately 60% to 80% of patients with medication-refractory OAB with limited risk of adverse events (Gormley et al., 2015; Gupta et al., 2015). The burden associated with weekly treatments during the 12-week induction phase and delayed response until weeks 8 to 10 can limit real-world compliance with treatment (Sirls et al., 2017).

Injection of botulinum toxin for OAB reduced urinary frequency by 29%, urgency by 38%, and daily incontinence episodes by 59% on pooled analysis of placebo-controlled trials (Mangera et al., 2014). Approximately one-quarter of patients may experience complete resolution of urinary incontinence (Chapple et al., 2013; Nitti et al., 2013a; Visco et al., 2012). The primary risks of botulinum toxin injection include symptomatic UTI in approximately 20% and the need to initiate intermittent catheterization in 0 to 12% in clinical trials (Mangera et al., 2014) but as many as 25% to 30% or more in “real-world” studies (Osborn et al., 2015; Siegel, 2017).

Sacral neuromodulation has been associated with a 5-year therapeutic success rate of approximately 70% to 80%, with mean reduction in daily urgency incontinence episodes of 2.0 +/−2.2 and voids of 5.4 +/−4.3 among participants completing 5-year follow-up (Siegel et al., 2018). Certain drawbacks of sacral neuromodulation include a revision rate exceeding 30% at 5 years resulting from adverse events such as undesirable change in stimulation, pain, or inefficacy. Furthermore, all patients wishing to maintain efficacy eventually require revision for battery replacement even if efficacy of the lead is maintained (Goldman et al., 2018).

Fourth-Line Therapy

In rare circumstances, symptoms of OAB are severe enough to warrant consideration of augmentation cystoplasty or urinary diversion. The impact of OAB on quality of life must be weighed against the short- and long-term risks associated with major surgery and those of alternative options including containment (i.e., pads/diapers) or indwelling catheters.

Key Points: Clinical Management

- First-line therapy comprises caffeine and fluid avoidance, weight loss, and behavioral therapy such as bladder training and pelvic floor muscle therapy.
- Second-line therapy consists of pharmacologic treatment with antimuscarinics (oral or transdermal) or β_3 agonists.
- Third-line therapy consists of tibial neuromodulation, botulinum toxin injection, and sacral neuromodulation. Shared decision making should guide treatment decisions.
- Fourth-line therapy comprises major surgery such as augmentation cystoplasty or urinary diversion. The risks of major surgery must be weighed against alternative options such as containment or indwelling catheterization.

Approach

The fifth ICI (Abrams et al., 2013) has produced a comprehensive review of the spectrum of incontinence management, weighted according to levels of evidence, and providing grades of recommendation (Abrams and Khoury, 2010). The ICI care pathways for the management of urinary incontinence in women, men, and the frail elderly are illustrated in Fig. 117.8. The AUA/SUFU Guideline on Non-Neurogenic Overactive Bladder in Adults also presents a Diagnosis and Treatment Algorithm for providers (https://www.auanet.org/Documents/education/clinical-guidance/Overactive-Bladder-Algorithm.pdf), as does the SUFU Overactive Bladder Clinical Care Pathway (https://sufuorg.com/docs/oab/sufu-oab-flyer.aspx). Themes common across diagnostic and treatment algorithms include the following:

	MEN	WOMEN	FRAIL ELDERLY
	INITIAL MANAGEMENT		
HISTORY	Urgency/frequency, with or without incontinence	Incontinence with mixed symptoms	Active case finding
CLINICAL ASSESSMENT	General assessment Urinary symptom assessment and symptom score (including FVC and questionnaire) Assessment QoL and desire for treatment Urinalysis ± urine culture; if infected, treat and reassess		Assess, treat and reassess potentially treatable conditions, including relevant comorbidities and ADLs Assess QoL, desire for treatment, goals for treatment, patient and caregiver preference Targeted physical exam including cognition, mobility, neurologic and rectal exams Urinalysis Consider FVC or wet checks, especially if nocturia present
	Physical examination; abdominal, rectal, sacral, neurologic Assessment of pelvic floor muscle function Assess postvoid residual volume	Physical examination; abdominal, pelvic and perineal *If appropriate* Cough test to demonstrate stress incontinence Assess estrogen status and treat as appropriate Assess voluntary pelvic floor muscle contraction Assess postvoid residual volume	
Presumed diagnosis	OAB with or without URGENCY INCONTINENCE	MIXED INCONTINENCE (treat most bothersome symptom first)	
Management	DISCUSS TREATMENT OPTIONS WITH THE PATIENT Lifestyle interventions Pelvic floor muscle training ± biofeedback Scheduled voiding (bladder training) Incontinence products Antimuscarinics (OAB ± urgency incontinence) and alpha adrenergic antagonists (if also bladder outlet obstruction)	Lifestyle interventions Pelvic floor muscle training for SUI or OAB Bladder retraining for OAB Antimuscarinic (OAB ± urgency incontinence)	Lifestyle interventions Behavioral therapies Consider additional trial of antimuscarinic drug Treat significant postvoid residual If insufficient improvement, reassess for treatment of contributing comorbidity ± functional impairment
	Failure		
	SPECIALIST MANAGEMENT		
HISTORY	Incontinence with urgency/frequency	Incontinence with mixed symptoms	
CLINICAL ASSESSMENT	Consider urodynamics and imaging of the urinary tract Urethrocystoscopy (if indicated)	Assess for pelvic organ mobility/prolapse Consider imaging of the urinary tract/pelvic floor Urodynamics	If continued insufficient improvement or severe associated symptoms are present, consider specialist referral as appropriate per patient preferences and comorbidity
Diagnosis	Mixed incontinence Urgency incontinence due to DO	Mixed incontinence (USI/DOI) DOI	
Management	Treat major component first	Treat most bothersome symptom first	

α-Blockers, 5ARI
Correct anatomic BOO
Antimuscarinics

If initial therapy fails:
Neuromodulation

Intermittent catheterization
Antimuscarinics

If initial therapy fails:
Stress incontinence surgery
Bulking agents
Tapes and slings
Colposuspension

If initial therapy fails:
Botulinum toxin
Neuromodulation
Bladder augmentation

Delirium
Infection
Pharmaceuticals
Psychological
Excess urine output
Reduced mobility
Stool impaction and other factors
Don't overtreat asymptomatic bacteriuria

FIG. 117.8 Overactive bladder in men, women, and the frail elderly; assessment and management derived from the respective algorithms of the fifth International Consultation on Incontinence (Abrams et al., 2013). *ADLs,* Activities of daily living; *5ARI,* 5α-reductase inhibitor; *BOO,* bladder outlet obstruction; *DO,* detrusor overactivity; *DOI,* detrusor overactivity incontinence; *FVC,* frequency volume chart; *OAB,* overactive bladder; *QoL,* quality of life; *SUI,* stress urinary incontinence; *USI,* urodynamic stress incontinence.

1. A careful clinical assessment to confirm the diagnosis of OAB and rule

out alternative diagnoses
2. Patient education regarding the diagnosis and treatment plan
3. Initial (first-line) treatment, consisting of lifestyle and behavioral modifications and behavioral therapy and/or pelvic floor muscle training
4. Second-line treatment, consisting of pharmacotherapy
5. Third-line or advanced therapies, consisting of tibial nerve stimulation, sacral neuromodulation, or chemodenervation

At each step in the pathway, symptoms, side effects, and patient preferences for continuation or alteration in treatment must be assessed. The minimum duration required to assess efficacy of behavioral therapies is variably reported at 4 to 12 weeks and pharmacologic therapies 4 to 12 weeks (Syan and Brucker, 2016). Progression to third-line treatments generally follows failure of conservative and pharmacologic management, although symptom severity and patient comorbidities may make extended pharmacologic treatment unfeasible. In such cases, earlier progression to third-line therapy may be appropriate.

The Underactive Detrusor

Christopher R. Chapple MD, FRCS (Urol), Nadir I. Osman MBChB (Hons), MRCS

An impaired ability to empty the bladder is common in both men and women with aging. It may be attributable to increased resistance of the bladder outlet and/or a reduction in the ability to generate an efficient bladder contraction, referred to as *detrusor underactivity (DUA)* by the International Continence Society (ICS), although the symptomatic condition could be labeled the *underactive bladder.* Increased bladder outlet resistance, far more common in men because of the effect of benign prostatic hyperplasia (BPH) with aging, has been the target of most therapeutic interventions for lower urinary tract symptoms (LUTS) in men. By contrast, DUA mostly lacks any effective treatment other than catheterization (preferably by intermittent self-catheterization [ISC]), when the postvoid residual (PVR) is raised. Despite its common prevalence, which increases with age, in patients with LUTS referred to urologists, the underlying cause and pathophysiologic mechanisms are poorly understood. Recently there has been a resurgence of interest in this poorly understood condition (Miyazato et al., 2013; Osman et al., 2014; van Koeveringe et al., 2011). In this chapter, we summarize and discuss the contemporary evidence relating to symptomatology, epidemiology, cause, diagnosis, and management of the underactive bladder.

Terminology, Definitions, and Symptoms

A confusing multitude of terms are used to describe impaired bladder voiding function, including *impaired detrusor contractility*, *detrusor areflexia*, and *detrusor failure.* **The ICS standardization document in 2002 termed the problem *DUA* defined on the basis of a urodynamic study (UDS) as “a contraction of reduced strength and/or duration, resulting in prolonged bladder emptying and/or failure to achieve complete bladder emptying within a normal time span”** (Abrams et al., 2002) **(Fig. 118.1A). What constitutes reduced strength, reduced length of contraction, or prolonged emptying is not specified. If no contraction occurs, the term *acontractile detrusor* is used (see Fig. 118.1B).** In clinical practice, it is important to distinguish this from an isolated inability to void during a UDS (or “bashful bladder”), which is common and often can be correlated with a history of being unable to void in public restrooms.

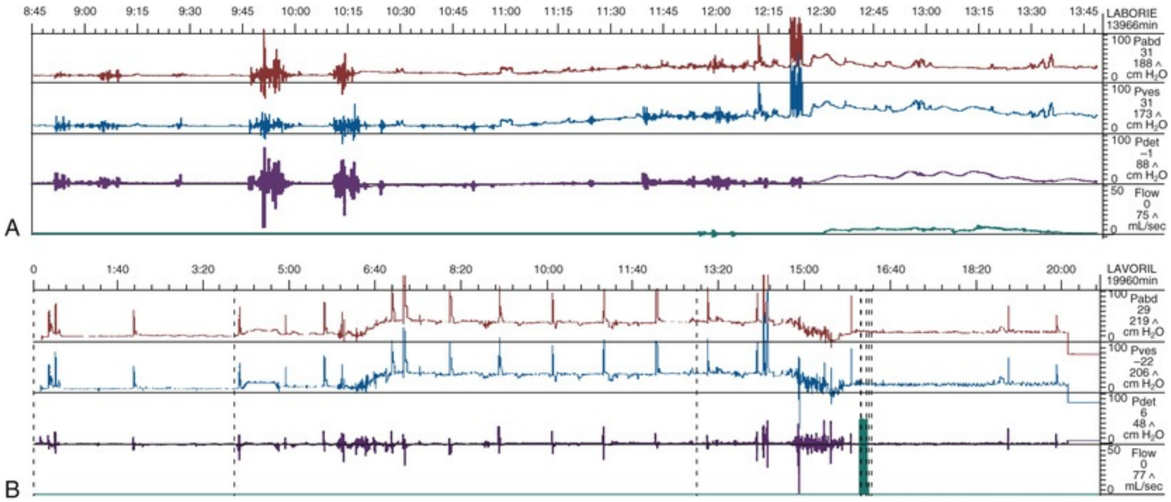

FIG. 118.1 Urodynamic traces. (A) A 67-year-old male patient with benign prostatic enlargement and predominant voiding lower urinary tract symptoms. The voiding phase demonstrates low detrusor pressure, prolonged detrusor contraction, and prolonged voiding time. The postvoid residual was 100 mL, and the diagnosis is detrusor underactivity. (B) A 29-year-old female patient with a history of lower back injury and urinary retention managed with intermittent self-catheterization. The diagnosis is acontractile detrusor. *Pabd,* Abdominal pressure; *Pdet,* detrusor pressure; *Pves,* intravesical pressure.

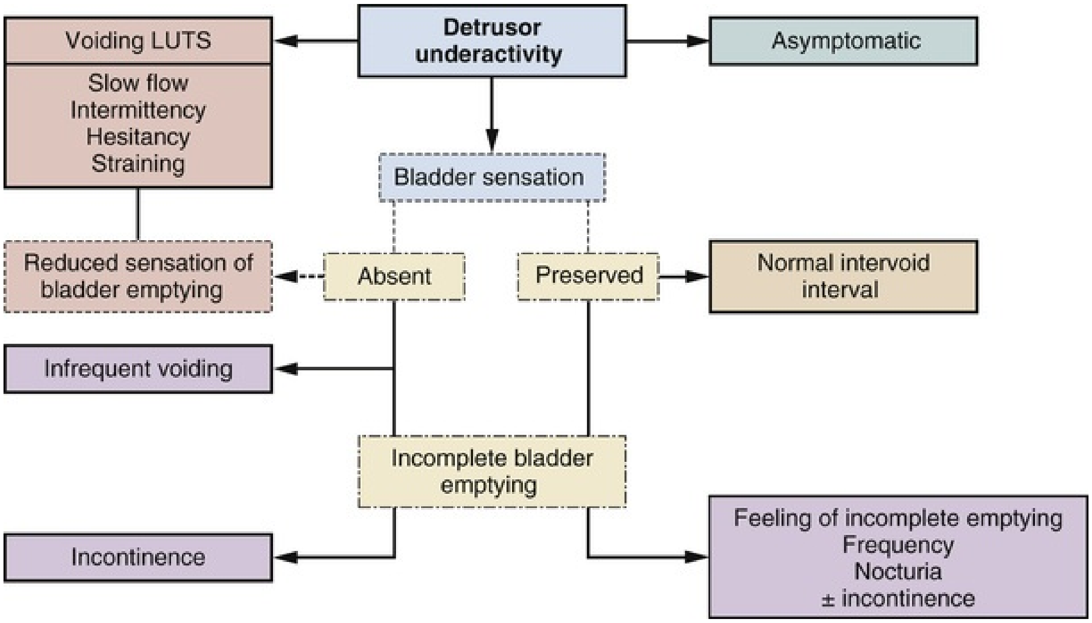
- Defining DUA in purely urodynamic terms is problematic, because this currently necessitates an invasive test that is neither available nor appropriate in all health care settings. These were some of the reasons why the overactive bladder (OAB) symptom complex was introduced as an adjunct to the urodynamic concepts. Nevertheless, the two situations are not entirely analogous, because OAB can be defined by the presence of urinary urgency (albeit variably correlated to detrusor overactivity [DOA]). **A symptom syndrome of underactive bladder is difficult to define because of the absence of individual symptoms that can be considered pathognomonic of the underlying detrusor abnormality. In particular, the symptoms of DUA are diverse and overlap significantly with those seen in OAB and are associated with bladder outlet obstruction (BOO)**. **During the voiding phase, patients may experience weak stream, intermittency, hesitancy, and straining. After voiding, some report a feeling of incomplete bladder emptying. In the storage phase, some experience urinary frequency and nocturia, whereas others may have a loss of the normal urge to void (the opposite of urinary urgency) and report infrequent voiding. In the presence of a very large PVR, patients may experience incontinence (especially during sleep).** One could speculate that the reason for these very different clinical pictures is related to the degree of residual bladder sensation, with patients with very poor sensation typically being infrequent voiders and those with intact sensation voiding frequently in the presence of a raised PVR (Fig. 118.2). A further problem at present relates to the lack of consensus over what represents a clinically significant residual volume in the bladder, with the suggestion being that the threshold is more than 40% of the functional capacity (volume voided + residual).



Voiding LUTS
Slow flow
Intermittency
Hesitancy
Straining
Detrusor underactivity
Asymptomatic
Bladder sensation
Reduced sensation of bladder emptying
Absent
Preserved
Normal intervoid interval
Infrequent voiding
Incomplete bladder emptying
Incontinence
Feeling of incomplete emptying
Frequency
Nocturia
± incontinence

FIG. 118.2 Lower urinary tract symptoms (LUTS) in detrusor underactivity (DUA). DUA may manifest with a spectrum of voiding, storage, and postmicturition LUTS or cause no symptoms. Patients with significantly impaired bladder sensation void infrequently and, if bladder emptying is reduced, may have incontinence, typically more pronounced during nighttime (urethral relaxation during sleep). Patients who have preserved bladder sensation can have a normal intervoid interval provided bladder emptying is normal. If bladder emptying is poor, these patients typically experience a sensation of incomplete emptying after voiding, urinary frequency, and nocturia ± incontinence. This wide variation in symptomatology and its overlap with LUTS/benign prostatic hyperplasia and overactive bladder hampers the development of a reliable symptom-based definition.

- Notwithstanding the above limitations, several attempts have been made at defining UAB. The most recent was proposed by Chapple et al. (2018) and has been accepted by the standardization committee of the international continence society (ICS).
- **Underactive bladder** is characterized by a slow urinary stream, hesitancy, and straining to void, with or without a feeling of incomplete bladder emptying, sometimes with storage symptoms. (Note: Underactive bladder occurs in association with diverse pathophysiologies and, based on current knowledge, there is no single distinguishing symptom. Storage symptoms are varied and

may be highly prevalent, including nocturia, increased daytime frequency, reduced sensation of filling, and incontinence. Underlying mechanisms of storage symptoms are diverse and are often related to a significant PVR urine volume.) Two recent studies (one quantitative, one qualitative) have suggested this definition is in keeping with the symptoms patients with urodynamic DUA are most likely to experience (Gammie et al., 2016; Uren et al., 2017).

Epidemiology

Epidemiologic studies have demonstrated that LUTS have a high prevalence in the population, increasing significantly with age. However, the extent to which DUA is a contributing factor is unknown. The Epidemiology of LUTS (EpiLUTS) study, conducted in the United Kingdom, United States, and Sweden, included 30,000 participants older than 40 years of age and showed that storage LUTS (occurring at least sometimes) are present in 45.7% of men and 66.8% of women. Voiding LUTS (occurring at least sometimes) were documented in 57.1% of men and 48% of women (Sexton et al., 2009). Postmicturition symptoms occur with a similar prevalence in both men and women. A more recent survey of 633 community dwelling individuals (mean age 74.3 years) reported a total of 23% had difficulty emptying their bladder (Valente et al., 2014). **Although it is clearly likely that multiple factors contribute to this clinical picture, it is difficult to establish on a population basis to what extent DUA is a cause of these symptoms because of the lack of a simple noninvasive marker.**

In men, voiding LUTS, raised PVR, or reduced urinary flow rate, individually or collectively, cannot be used as proxy measures for DUA, because they could be attributed to BOO. Similarly, in women, voiding LUTS such as straining often can occur in the context of frequency and low voided volumes associated with OAB. However, if voiding LUTS occur in association with more objective evidence such as reduced flow rate and raised PVR, underlying DUA becomes more likely as a result of the extremely low incidence of BOO in women (2.7% to 8% of those referred for UDS) (Carr and Webster, 1996).

In the absence of reliable epidemiologic data, clinical studies indicate that DUA is very common in patients with LUTS referred for urodynamic assessment, particularly in the older age groups (Table 118.1). **DUA is diagnosed in 9% to 28% of males younger than 50 years of age and 48% in those older than 70 years of age. In females, DUA is present in 12% to 45%, being more common in elderly nursing home residents who often have concomitant DOA, an entity described as detrusor hyperactivity impaired contractility (DHIC)** (Resnick et al., 1989). It must be borne in mind that these data cannot be extrapolated to the general population and are limited by the inconsistency in definitions used in these studies, the populations studied, and the post-hoc data interpretation.

TABLE 118.1

Prevalence of Detrusor Underactivity in Clinical Studies

STUDY	POPULATION	SIZE	AGE RANGE OR MEAN AGE (YEARS)	DIAGNOSTIC CRITERIA	PREVALENCE OF DUA + (% OF ACONTRACTILE DETRUSORS)
Fusco et al., 2001	Male	541	26–89	Pdet@Qmax ≤30 cm H_2O and Qmax ≤12 mL/sec	10
Kuo, 2007b	Male	1407	46–96	Relaxed sphincter EMG with open membranous urethra during voiding and low flow rate	10.6
Nitti et al., 2002	Male	85	18–45	Bladder outlet obstruction index <20 cm H_2O and uroflow <12 mL/sec	9
Wang et al., 2003	Male	90	18–50	Pdet@Qmax <30 cm H_2O and Qmax <15 mL/sec	10
Kaplan et al., 1996	Male	137	18–50	Pdet@Qmax <45 cm H_2O and Qmax <12 mL/sec	23 (5)
Karami et al., 2011	Male	456	18–40	ICS definition	12.9 (10.5)
Abarbanel and Marcus, 2007	Male	82	>70	Pdet@Qmax <30 cm H_2O and Qmax <10 mL/sec	48
	Female	99	>70		12
Jeong et al., 2012	Male	632	>65	Bladder contractility index <100 (men)	40.2

	Female	547	>65	Qmax ≤12 mL/sec and Pdet@Qmax ≤10 cm H_2O (women)	13.3
Resnick et al., 1989	Male	17	87	In the absence of obstruction, underactive detrusor: “Failure to empty in the absence of an increase in abdominal pressure”	41.2
	Female (institutionalized)	77		DHIC: “Involuntary detrusor contraction that emptied less than half of volume instilled”	37.7
Resnick et al., 1996	Female (institutionalized)	97	87.6	“Reproducible failure of the involuntary contraction to empty at least half of bladder contents in the absence of straining, urethral obstruction, and detrusor-sphincter dyssynergia”	45
Groutz et al., 1999	Female	206	62.6 ± 15.8	ICS definition	19
Valentini et al., 2011	Female	442	>55	“Impaired detrusor contraction leading to prolonged voiding time and high residual volume”	13.8

DHIC, Detrusor hyperactivity impaired contractility; *DUA,* detrusor underactivity; *EMG,* electromyography; *ICS,* International Continence Society; *Pdet,* detrusor pressure; *Qmax,* maximal urinary flow rate.

From Osman NI, Chapple CR, Abrams P, et al. Detrusor underactivity and the underactive bladder: a new clinical entity? A review of current terminology, definitions, epidemiology, aetiology, and diagnosis. *Eur Urol* 65:389–398, 2014.

One of the largest clinical urodynamic series demonstrated that DUA often coexists with other lower urinary tract dysfunctions (LUTDs) in the elderly (Jeong et al., 2012). In their study of 1179 patients older than 65 years of age, 46.5% of males with DUA also had DOA or BOO, and 72.6% of the females with DUA also had DOA or urodynamic stress urinary incontinence (Fig. 118.3). In our opinion, this is further support for the case for urodynamic assessment before surgical intervention for LUTS in this group.

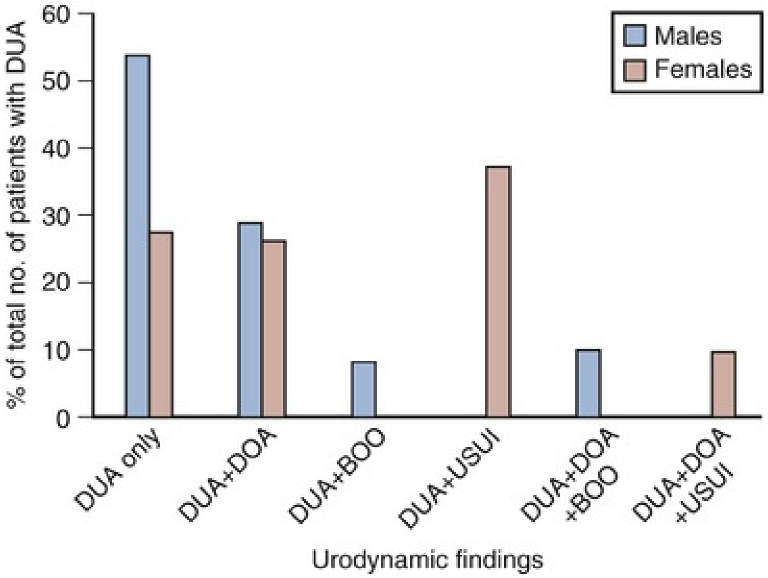


FIG. 118.3 The overlap between detrusor underactivity (DUA), detrusor overactivity (DOA), and bladder outlet obstruction (BOO) in 1179 patients (632 men and 547 women) older than 65 years of age in a Korean clinical series of urodynamic studies. DUA was defined as a bladder contractility index less than 100 in men and Qmax 12 mL/sec or less and Pdet@Qmax 10 cm H_2O or less in women. In total, 40.2% of men and 13.3% of women were classified as having DUA. The data suggest a significant overlap between DUA and other urodynamic diagnoses. *USUI,* Urodynamic stress urinary incontinence. (Raw data provided by Dr. Sang Eun Lee. From Jeong SJ, Kim HJ, Lee YJ, et al. Prevalence and clinical features of detrusor underactivity among elderly with lower urinary tract symptoms: a comparison between men and women. *Korean J Urol* 53:342–348, 2012.)

Very little is known of the natural history of DUA. In a 10-year study of 69 men with non-neurogenic DUA (with a maximal urinary flow rate [Qmax] of <15 mL/sec and detrusor pressure [Pdet] at Qmax [Pdet@Qmax] of <40 cm H_2O) managed conservatively, there was minimal symptomatic or urodynamic progression (Thomas et al., 2005b). In this cohort, 11 patients underwent transurethral resection of the prostate (TURP), 3 for acute urinary retention and 8 for worsening LUTS (all of whom showed no change in Qmax preoperatively compared with baseline values).

Key Points: Terminology, Definitions, Symptoms, and Epidemiology

- DUA is a common clinical problem associated with a range of storage, voiding, and postmicturition LUTS.
- The population prevalence of DUA is not known because of the lack of a noninvasive marker.
- DUA affects 9% to 28% of men younger than 50 years of age and 48% of those older than 70 years of age undergoing UDS and is more prevalent among the institutionalized elderly.
- In women, DUA is found in 12% to 45% undergoing UDS and is more prevalent among the institutionalized elderly.
- DUA commonly coexists with other LUTDs.

Etiopathogenesis

DUA occurs in both sexes and diverse clinical groups. Several distinct etiologic factors are recognized, such as diabetes mellitus and cauda equina compression. **In clinical practice, many patients do not have any obvious cause for DUA, neurologic or otherwise, suggesting that DUA may occur secondary to common age-related changes. In particular, an age-related decline in detrusor function with normal aging is likely, although it has not been conclusively demonstrated.**

Direct measurement of the contractility of bladder muscle strips from rodents, comparing younger to older animals, has yielded contradictory results that are difficult to extrapolate to humans because of differences in functional innervation. The few studies that used human bladder muscle strips often have failed to demonstrate a decline in contractile responses to electrical stimulation and a variety of agonists (Fry et al., 2011; Mark et al., 1992; Yoshida et al., 2001). Some clinical urodynamic data suggest an age-related reduction in Pdet and flow rate accompanied with an increase in PVR (Pfisterer et al., 2006; Smith et al., 2009; Valentini et al., 2011). Most studies have included symptomatic individuals with probable underlying pathophysiologic abnormalities that could be expected to progress with time. **It is to be expected that there would be a more pronounced decline in detrusor contractility in men because of bladder wall changes (increased connective tissue and reduced smooth muscle) occurring as a result of BOO; however, these changes are also seen in women, suggesting that they may be partly attributable to normal aging** (Holm et al., 1995; Lepor et al., 1992) **(Fig. 118.4A–C).**

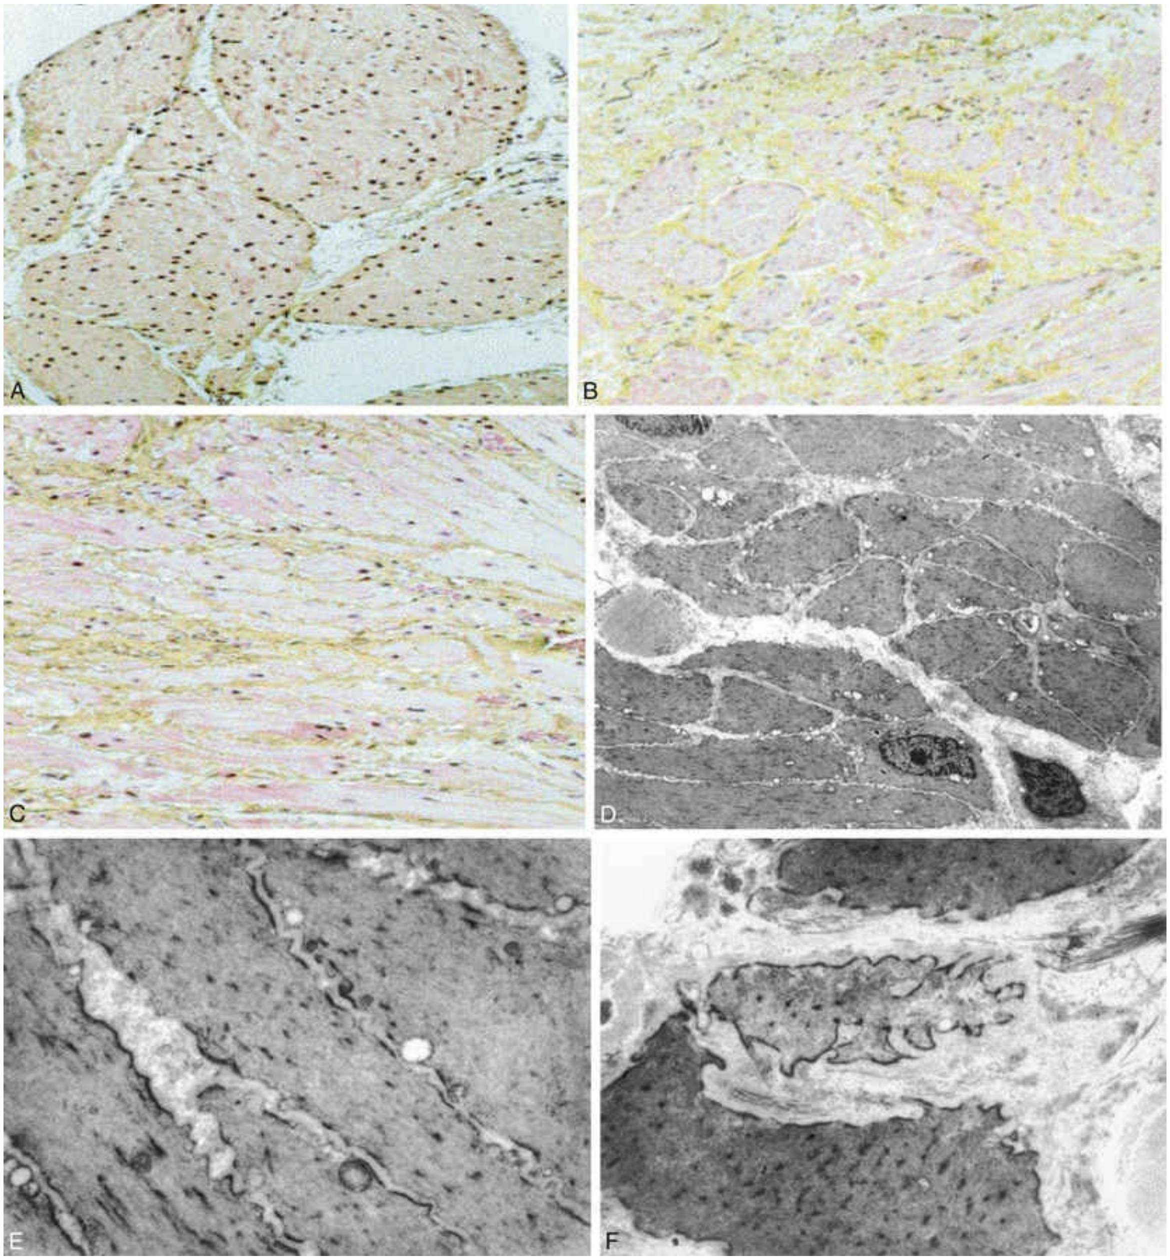

FIG. 118.4 Morphologic detrusor changes in aging and disease. (A–C) Light microscopy. (A) Normal detrusor. (B) Male patient with bladder outlet obstruction showing an increase in muscle mass and increase in fibrous tissue deposition inside and between muscle bundles. (C) Elderly female patient without lower urinary tract symptoms showing similar deposition of fibrous tissue, suggesting extracellular matrix changes also occur with aging. (D–F) Electron microscopy. (D) Normal detrusor muscle showing two muscle bundles. A wide collagen-rich septum dividing the bundles is seen. Within the bundles are individual fascicles separated by a thin microseptum (magnification ×6000). (E) Normal muscle cells at higher power magnification; smooth intact sarcolemma with a thin interstitium between adjacent cells. (F) Degeneration pattern. A disruptive cell, with a shriveled appearance and sarcolemma breakdown, with debris and

collagen deposition in the interstitium. (A to C from Nordling J. The aging bladder: a significant but underestimated role in the development of lower urinary tract symptoms. *Exp Gerontol* 37:991–999, 2002; D to F from Brierly RD, Hindley RG, McLarty E, et al. A prospective controlled study of ultrastructural changes in the underactive detrusor. *J Urol* 169:1374–1378, 2003.)

The mechanisms by which different causes result in DUA can be classified as (1) myogenic, affecting the cellular functions of detrusor myocytes or the surrounding extracellular matrix or (2) neurogenic, affecting the afferent pathways, efferent pathways, or brain circuits involved in the micturition reflex. (These mechanisms and the probable major etiologic factors are summarized in Fig. 118.5.)

FIG. 118.5 Etiopathogenesis of detrusor underactivity (DUA). The mechanisms by which the likely major etiologic factors lead to DUA. Bladder outlet obstruction and normative aging are probable rather than definite factors. *BPH,* Benign prostatic hyperplasia; *PAG,* periaqueductal gray; *PMC,* pontine micturition center.

Myogenic Factors

Processes that alter the normal structure and function of the detrusor muscle extracellular matrix may result in diminution of transmitted contractile force. The intrinsic ability of detrusor muscle cells to generate contractile activity may be compromised by dysfunction of cellular mechanisms (e.g., ion storage/exchange, excitation-contraction coupling, calcium storage, energy generation) such that even in the presence of normal extrinsic neuronal activity, a reduced contraction may occur (Brierly et al., 2003).

Morphologic changes have been reported to occur in the detrusor with normal aging and disease. Elbadawi et al. proposed that distinct ultrastructural patterns observed by electron microscopy characterized the normally contractile aging detrusor and different bladder dysfunctions, including DUA (Elbadawi et al., 1993a, 1993b, 1993c). Although the applicability of this classification system is disputed, other groups have noted similar findings (Brierly et al., 2003; Hindley et al., 2002). This degeneration pattern, which consists of widespread disrupted detrusor myocytes and axonal degeneration, has been associated with DUA (Elbadawi et al., 1993a). Whether detrusor myocyte disruption is the cause of DUA or a consequence of a pathologic insult is not clear (see Fig. 118.4D–E).

Neurogenic Factors

Brain Circuits

The central neural control mechanism governing micturition involves key processes including perception and integration of storage and voiding that, if disturbed, may result in DUA (Suskind and Smith, 2009). The micturition reflex is facilitated by the spino-bulbo-spinal pathway passing through the sacral parasympathetic nucleus and the pontine micturition center (PMC). The PMC receives input from higher centers in the cerebral cortex and in particular the limbic system. Many insights have been gained from functional neuroimaging studies in animals (de Groat et al., 1998; Sugaya et al., 2003, 2005). Certain populations of PMC neurons (“direct neurons”) appear to become activated immediately before and during reflex bladder contractions, whereas outside these periods they are completely inactive. A large number of these neurons pass to the lumbosacral spinal cord, suggesting a role in the micturition reflex. Human functional neuroimaging suggests similar areas of the brainstem and cortex are implicated—the insula, hypothalamus, periaqueductal gray, and PMC (Blok et al., 1997). Any lesion affecting these regions could in theory result in DUA, albeit a clinical correlation between the site of a neurologic lesion and the urodynamic finding is not always apparent in all diseases (Kim et al., 1998).

Bladder Efferent Pathways

Interruption or impairment of efferent signaling in the sacral cord, sacral roots, and pelvic nerves may manifest as absent or reduced detrusor contraction. There is evidence to suggest that a reduction in autonomic innervation occurs in the human bladder as a consequence of normal aging (Gilpin et al., 1986). A range of diseases and injuries can result in disturbance of efferent signaling (discussed later in this section).

Bladder and Urethral Afferent Pathways

Intact bladder sensation is critical to the functioning of the efferent limb of the micturition reflex. Bladder afferents monitor both volumes during bladder filling in the storage phase of the micturition cycle and the magnitude of detrusor contractions during the voiding phase. Urethral afferents have an important role in the perception of both flow through the urethra and detrusor contraction (Bump, 2000; Feber et al., 1998)**. An impairment in afferent function (from bladder or urethra) is likely to reduce or prematurely end the micturition reflex, leading to impairment or loss of voiding efficiency** (Suskind and Smith, 2009). There is evidence that normal aging is associated with a decline in sensory function in the lower urinary tract. In support of this, an age-related increase in the thresholds for reaching bladder capacity was observed in women (Pfisterer et al., 2006, 2007) and functional magnetic resonance imaging in asymptomatic older people has shown a reduced response to bladder filling in the insula (the region that maps visceral sensation).

Given that both tissue changes and a decline in sensory function appear to occur with aging, it is likely that both factors contribute to DUA in the elderly. An interesting hypothesis that integrates both aspects has been proposed (Smith, 2010). It is based on the concept that afferent outflow is a function of bladder wall stress and suggests that increased connective tissue deposition and smooth muscle disruption results in a loss of bladder elasticity that leads to changes in the normal passive compliance curve. There would also be impairment of normal sensory innervations resulting from connective tissue infiltration into the bladder wall. Conceptually the bladder progressively loses the property of receptive relaxation and becomes more akin to a stiff balloon. Such a stiff-walled bladder will exhibit a precipitous rise in wall stress with physiologic filling. Clinically this would be manifested by delayed bladder sensation, and soon after this, the sensation of urgency as the functional bladder capacity is reached. After a small volume of urine is passed, wall stress is dramatically reduced, with a reduction in afferent stimulation resulting in premature termination of the detrusor contraction before the bladder is emptied and an increased PVR. A small clinical study in which DUA was characterized by a strong desire to void at higher volume, similar contractility (as assessed by the Watts factor), but smaller voided volumes and elevated PVRs as compared with other LUTDs, suggest the above hypothesis may represent the situation in a substantial proportion of patients with DUA (Smith et al., 2015).

The important role of the urothelium in both normal and abnormal bladder functioning is increasingly recognized. Several recent studies looking at bladder biopsies in patients with DUA suggest that impaired urothelial signaling and sensory transduction pathways may have a role in the pathophysiology (Cho et al., 2017; Jiang and Kuo, 2017a). It is, however, difficult to establish whether these changes are causative or an effect of other processes (e.g., BOO). Ultimately, it will be difficult to establish causality or effect in the context of human studies, and animal models are necessarily limited by differences in functional innervation between animals and humans.

Specific Etiologic Factors

See Box 118.1.

Box 118.1

Etiologic Factors

Idiopathic

Normal aging
Unknown factor in younger people

Neurogenic Injury and Disease

Vascular

    - Stroke (early phase)
- Degenerative
    - Parkinson disease
    - Multisystem atrophy
- Demyelinating neuropathies
    - Multiple sclerosis
- Peripheral neuropathies
    - Guillain-Barré syndrome
    - Neurosyphilis (tabes dorsalis)
    - Herpes-zoster and herpes simplex
    - Diabetes mellitus
    - Acquired immunodeficiency syndrome
- Spinal cord and cauda equina
    - Intravertebral disk prolapse
    - Cauda equina lesions
    - Spinal cord tumors
    - Spinal canal stenosis
    - Spinal cord injury
    - Sacral fracture
- Pelvic fracture
- Pudendal nerve injury (bilateral)

Myogenic

- Bladder outlet obstruction
- Diabetes
- Pelvic arterial ischemia

Iatrogenic

- Radical pelvic surgery
- Radical prostatectomy
- Radical hysterectomy
- Anterior resection, abdominoperineal resection
- Detrusor myomectomy
- Intravesical phenol injections
- Radiation therapy

Functional

- Fowler syndrome
- Dysfunctional voiding

Pharmacotherapy

- Drugs with anticholinergic effects
  - Antimuscarinics
  - Antihistamines
  - Antipsychotics
  - Anti-Parkinson medications
  - Antispasmodics
  - Tricyclic antidepressants
  - Opioids

Bladder Outlet Obstruction

DUA also may occur as consequence of a series of changes in the detrusor induced by the increased work requirements to overcome BOO. In rodent models of partial BOO, the sequence of events leading to DUA is well described and has been separated into three stages. Initially a surgically created BOO (e.g., ring or ligature) increases bladder outlet resistance and results in bladder distention. The detrusor muscle then undergoes compensatory hypertrophy and hyperplasia, with bladder weight increasing sharply over the next few weeks before stabilizing. During this time, tissue blood supply also increases. The contractile function at this point is almost normal, and the bladder is said to have entered the compensated stage in which mass and function remain relatively stable. After a period of variable length, detrusor contractile function declines and bladder emptying is impaired, marking the decompensation phase (Levin et al., 1992; Saito et al., 1997). This is characterized by reduced response to electrical stimulation and agonists and replacement of bladder muscle with connective tissue (fibrosis). Typically, if the obstruction is not relieved before the stage of decompensation and connective tissue deposition, permanent contractile dysfunction ensues. In such an obstructed bladder, laser Doppler estimation of blood flow has demonstrated this to be decreased, further contributing to the bladder wall dysfunction by a direct effect on both neural and muscular dysfunction (Greenland and Brading, 1996). Other work has demonstrated that there is denervation of the bladder as a consequence of BOO in both humans and in an animal model (Harrison et al., 1987; Sibley, 1987).

Clearly the hypothesis to explain the sequential changes observed in animals centers on ischemic/reperfusion injury and pathologic connective tissue infiltration consequent on increased intravesical pressure being necessary to overcome outlet resistance. This results in increased bladder wall tension during contraction (the law of Laplace). This leads to compression of bladder wall vessels, tissue ischemia, and hypoxia. Cycles of ischemia and reperfusion during the micturition cycle (as the bladder empties and then fills) lead to generation of reactive oxygen species (Erdem et al., 2005) and release of free intracellular calcium. These factors cause activation of proteases, phospholipases, and membrane lipid peroxidation, which damages cellular and subcellular membranes, including nerve cells, synaptic membranes, mitochondria, and sarcoplasmic reticulum. The outcome of these processes is impaired cellular function and denervation, leading to decompensation of detrusor function (Schroder et al., 2001).

Relating the insights from this work to humans is problematic, because the animals studied are usually immature and often female; the obstruction is acute and certainly not representative of the clinical scenario. Indeed, the sequential changes that have been described, with consistency, do not correlate with the diverse outcomes men with BOO experience clinically. In addition, this sequence of events is not seen in patients presenting with a urethral stricture and does not explain the genesis of the similar bladder dysfunction seen clinically in female patients.

A longitudinal study has demonstrated that prolonged BOO commonly does not necessarily result in clinical decompensation. In a cohort of 170 men with BOO followed for a mean of 13.9 years, no significant deterioration was found in urodynamic parameters (no change in pdet@Qmax (detrusor pressure at maximum flow) and a reduction in Qmax (maximum flow rate) of only 1 mL/sec), and only 17% required any form of intervention (Thomas et al., 2005a). Of men who decompensate their bladders acutely (i.e., develop acute urinary retention), most have preserved detrusor function. Even among men with chronic retention, there are some who have preserved contractility and typically poor compliance and upper renal tract changes (high-pressure chronic retention) (Djavan et al., 1997; George et al., 1983). The pathophysiologic explanation for these divergent clinical outcomes remains unknown.

Some aspects of the pathophysiology relating to BOO remain unclear.

Animal models do not predict or explain what is seen in the clinical setting. It is likely that the clinical picture in any individual patient is multifactorial and thus unlikely to be explained by any single hypothesis.

Diabetes Mellitus

Diabetes mellitus may impair detrusor function through a combination of myogenic and neurogenic mechanisms. Diabetes-induced bladder dysfunction (DBD), classically termed *diabetic cystopathy,* results in a reduction in emptying efficiency in a time-dependent fashion during the course of the disease (Lee et al., 2004; Lifford et al., 2005). This is traditionally attributed to an autonomic neuropathy occurring as a result of axonal degeneration and segmental demyelination resulting in diminished bladder sensation (Hill et al., 2008). The mechanisms underlying this process are thought to occur as consequences of hyperglycemia. These include activation of the polyol pathway, increases in the generation of free radicals, activation of protein kinase C, and formation of advanced glycated end products (Daneshgari et al., 2009; Miyazato et al., 2013). It has been suggested that a reduction in nerve growth factor (essential for maintaining normal sympathetic and sensory nerve function) is also implicated in DBD. In support of this, studies in streptozotocin-induced diabetes mellitus in rats have shown reduced levels of nerve growth factor in the dorsal root ganglia associated with increased PVR and bladder capacity (Hellweg et al., 1994; Sasaki et al., 2002).

DBD also may result from detrusor myocyte dysfunction occurring as a result of alterations in intercellular connections and excitability, intracellular signaling, receptor density, and distribution. These mechanisms are poorly understood; most insights are derived from animal studies, which have demonstrated both increases and reductions in bladder contractility. Daneshgari et al. (2009) suggested this may be explained by time-dependent changes occurring in the bladder wall, the DBD temporal theory. This theory postulates that initially osmotic diuresis induced by hyperglycemia causes bladder wall stretching, which with increased intravesical pressure results in compensatory bladder hypertrophy. This stage would correspond clinically to storage symptoms early in the disease time course. It is suggested that as the disease progresses, accumulation of toxic products of oxidative stress results in bladder decompensation, clinically manifested as poor bladder sensation and impaired voiding function with associated LUTS.

Neurologic Disease or Injury

A range of neurologic diseases or injuries affecting the brain, spinal cord, or peripheral nerves can lead to DUA (see Box 118.1). Although neurogenic DOA is the most common chronic urologic sequela of cerebrovascular accident, in the acute phase approximately one-half of patients develop urinary retention (attributed to "cerebral shock"); 75% of these have acontractile detrusors (Burney et al., 1996). Similarly, in Parkinson disease DUA is far less common than DOA, occurring in less than 20% of cases (Araki et al., 2000).

Anticholinergic parkinsonian medication may be an important contributor; in a study in which these were withdrawn before urodynamic assessment, DUA was not demonstrated in any patient (Stocchi et al., 1997). Multisystem atrophy, otherwise known as Shy-Drager syndrome, is a condition often confused with Parkinson disease, in which 52% to 95% of patients demonstrate DUA on UDS (Bloch et al., 2010; Yamamoto et al., 2014) as a result of atrophy of efferent parasympathetic nerves, and clinically the majority of these patients develop urinary retention. DUA occurs in 20% of patients with multiple sclerosis (Litwiller et al., 1999), particularly when plaques affect the lumbosacral cord.

Injury at the level of lumbosacral spinal cord, the cauda equina, and sacral and pelvic nerves can occur as a result of trauma or a prolapsed intervertebral disk and also commonly results in DUA related to cauda equina syndrome. In particular, radical pelvic surgery can lead to injury to the pelvic plexus (located near the anterolateral wall of the lower rectum) or postganglionic fibers that traverse the lateral wall of the upper vagina.

A systematic review found that the overall incidence of LUTD after radical hysterectomy was 72% (Plotti et al, 2011). Although high incidences were reported in older series of patients undergoing rectal cancer surgery, more recently lower rates have been reported (<5%), which can be attributed to the adoption of nerve-sparing techniques (Maurer et al., 2001). The true incidence of DUA in this context is difficult to define because of the lack of studies correlating preoperative and postoperative urodynamic findings. Nevertheless, many patients appear to recover bladder function by 1 year after surgery. In support of this, a study of feline pelvic plexus extirpation suggests this may be caused by restitution of intrinsic cholinergic nerves and muscle cell regeneration after an initial injury-related degeneration (Elbadawi et al., 1988).

In neurologic disorders associated with infective causes, DUA can be either entirely reversible, such as in Guillain-Barré syndrome and herpes zoster (shingles), or permanent, as seen with progressive problems such as acquired immunodeficiency syndrome or neurosyphilis (tabes dorsalis), as was common in the preantibiotic era.

Pelvic Arterial Ischemia

Aging and environmental factors such as smoking and diet are associated with an increased prevalence of atherosclerosis, metabolic syndrome, hypertension, hyperlipidemia, and diabetes mellitus. The association of LUTS with advancing age has led to the hypothesis that vascular risk factors for atherosclerosis, resulting in chronic bladder ischemia, may play a role in the development of LUTS and other disorders such as erectile dysfunction. Several animal studies have shown that induced pelvic arterial insufficiency leads to bladder wall ischemia and decreased oxygenation (Azadzoi et al., 1999a, 1999b). This results in oxidative stress causing ultrastructural damage and denervation (Azadzoi et al., 2010, Nomiya et al., 2014) leading to features of DUA in some animal studies (Nomiya et al., 2012, Zhao et al., 2016).

Key Points: Eitopathogenesis

- The etiopathogenesis of DUA is incompletely understood; a diverse range of factors and pathophysiologic mechanisms are likely to be implicated.
- Confirmed etiologic factors include neurologic injury/disease and diabetes mellitus; BOO, aging, and artherosclerosis are probable rather than definite contributory factors.
- These factors may cause DUA by impairing or disrupting processes that are essential for the generation of an efficient voiding contraction.
- The pathophysiologic mechanisms can be classified as follows:
  - Myogenic: Affecting detrusor myocytes or their surrounding extracellular matrix
  - Neurogenic: Affecting the central neural control mechanisms governing the voiding reflex by an action on either afferent or efferent nerves

Diagnosis

The only accepted modality for clinically estimating detrusor voiding function is an invasive UDS; however, there are currently no universally agreed criteria for diagnosing DUA. Current methods of estimating detrusor voiding function almost exclusively focus on detrusor contraction strength (Table 118.2), neglecting other potentially important aspects such as the speed and sustainability of a detrusor contraction.

TABLE 118.2

Summary of Diagnostic Methods and Criteria

TYPE	METHOD	ADVANTAGES	LIMITATIONS
Mathematical calculations	Watts factor	Measure of bladder power Minimally dependent on volume of urine Not affected by presence of BOO	Lengthy and complex calculation No validated thresholds Does not measure sustainability of contraction
	Detrusor shortening velocity	May identify early-stage DUA	
Indices	Detrusor contraction coefficient (DECO)	Simple to use Measurement easy to obtain Estimation of isovolumetric contraction	Does not measure sustainability of contraction May not be applicable to other groups
	Bladder contractility index (BCI)		
Occlusion testing	Voluntary stop test	Real-time indication of isovolumetric contraction strength No calculations	Uncomfortable or painful for patients Impractical No information on sustainability of contraction (in continuous occlusion) May underestimate isovolumetric pressure
	Mechanical stop test		
	Continuous occlusion		

			(stop test) Unusable in some patient groups
Ranges of urodynamic measurements	Pdet@Qmax (e.g., <40) Qmax (e.g., <15)	Simple to use	No widely accepted “normal” ranges Underestimate contraction strength Does not conceptually consider coexistence of BOO and DUA

BOO, Bladder outlet obstruction; *DUA,* detrusor underactivity; *Pdet,* detrusor pressure; *Qmax,* maximal urinary flow rate.

From Osman NI, Chapple CR, Abrams P, et al. Detrusor underactivity and the underactive bladder: a new clinical entity? A review of current terminology, definitions, epidemiology, aetiology, and diagnosis. *Eur Urol* 65:389–398, 2014.

Detrusor Contraction Strength

A detrusor contraction generates both pressure and flow (Griffiths, 2003); thus many authors have used two parameters to diagnose DUA: Qmax and Pdet@Qmax. Reductions in both are considered to be below the lower limits of the normal ranges for the particular patient group. For men, these ranges were derived from series of patients undergoing bladder outlet surgery (Abrams and Griffiths, 1979; Schäfer et al., 1989). In healthy men and women, these ranges are less well characterized (Pfisterer et al., 2006; Rosario et al., 2008; Schmidt et al., 2002).

There are two limitations with this approach. First, it is likely to underestimate the contraction strength because of bladder outlet relation (BOR), the normal inverse relationship between Pdet and urine flow (Griffiths, 1973). The BOR is an adaptation of the Hill equation for actively contracting muscle and can be summarized as during voiding when flow is low the pressure is high and vice versa. On this basis, the Pdet@Qmax actually represents the point of least pressure. Second, the variability in bladder outlet resistance that also can affect flow rate is not considered. The clinical implications of this are that when Pdet is low, a low Qmax also can be attributed to increased outlet resistance (e.g., BOO caused by BPH), or alternatively a normal Qmax can result from reduced outlet resistance (e.g., postprostatectomy incontinence).

To more accurately assess contraction strength, methods that estimate isovolumetric pressure were developed. These are based either on post-hoc

mathematical calculations or volitional or mechanical interruption to the flow of urine during UDS (Griffiths, 2004)**. Many of these are complicated, time-consuming, or impractical, limiting their use in clinical practice.**

The Watts factor (WF) is an estimate of the power per unit area of bladder surface that is generated by the detrusor, corrected for the finite power required for either isometric contraction or for shortening against no load. It is calculated by the following formula:

$$\mathrm{WF} = [(\mathrm{Pdet} + a)(\mathrm{Vdet} + b) - ab]/2\pi$$

where Vdet is detrusor shortening velocity, and *a* and *b* are fixed constants (*a* = 25 cm H_2O, *b* = 6 mm/sec), derived from experimental and clinical data (Griffiths, 1991). Throughout micturition, the WF varies because of the variation in Pdet and Vdet; the points proposed to best represent detrusor contraction strength is the point at which the WF peaks, the maximal WF (WFmax). The major advantages of the WF are that it minimally depends on volume (Griffiths, 1991) and that it is not affected by increased outlet resistance (Lecamwasam et al., 1998). However, as of yet there are no validated cutoffs for the normal range, but based on expert opinion a WFmax of 7 W/m^2 was deemed to represent the threshold for reduced contractility (van Koeveringe et al., 2011), although some authors use a value of 10 W/m^2 (Mitsui et al., 2012). Ultimately, the WF found little use in everyday clinical practice because of the complexity of the calculation, and, as with all current measures, it does not consider the sustainability of a contraction.

Schäfer (1995) proposed an alternative method of estimating isometric contraction strength that is based on superimposing the BOR on his pressure-flow nomogram. The BOR is simplified to a straight line and “projected” back to the *y*-axis (Pdet) from the point representing Pdet@Qmax to obtain the isovolumetric pressure (Fig. 118.6). This projected isovolumetric pressure (PIP) can be calculated by the following formula:

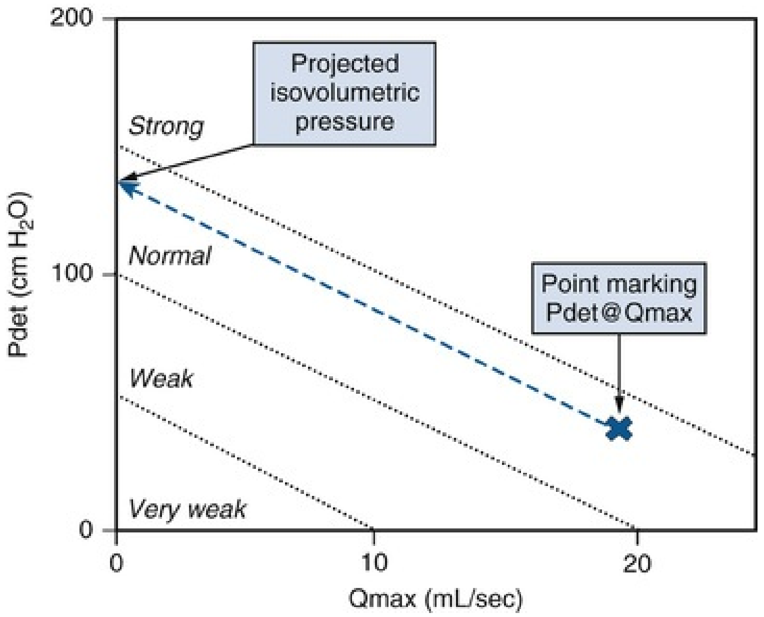

FIG. 118.6 Method of determining the projected isovolumetric pressure. The point marking the detrusor pressure (Pdet) @Qmax is plotted on Shäfer's contractility nomogram and is projected back to the *y*-axis. In this case, the pressure is 130 cm H_2O, which is in the normal contractility range.

$$\mathrm{PIP} = \mathrm{Pdet}\ @\ \mathrm{Qmax} + \mathrm{KQmax}$$

where K is a fixed constant representing the slope of the BOR (Schäfer, 1995). The value of K depends on the specific population studied. In men with BPH, it is taken as 5 cm H_2O/mL/sec, whereas in older women 1 cm H_2O/mL/sec was found to be more accurate (Griffiths, 2004).

Based on this, the suggested formula for use in men in clinical practice is as follows:

$$\mathrm{PIP} = \mathrm{Pdet}\ @\ \mathrm{Qmax} + 5\ \mathrm{Qmax}$$

A PIP greater than 150 represents strong contractility, 100 to 150 normal contractility, 50 to 100 weak contractility, and less than 50 very weak contractility. The corresponding BORs at these cutoffs were plotted on the Schäfer pressure-flow nomogram to give subdivisions for contractility (see Fig. 118.6).

Although there are two other reported variations of PIP, all three are essentially the same. **The detrusor coefficient is the PIP divided by 100, where a value less than 1 signifies weak contraction.**

$$\mathrm{PIP} = \mathrm{Pdet} @ \mathrm{Qmax} + 5\ \mathrm{Qmax}/100$$

The bladder contractility index, described by Abrams, is calculated using the same formula as PIP and includes three groupings (strong >150, normal 100 to 150, and weak <100) (Abrams, 1999). Evidently all these methods are fairly easy and quick to calculate but tend to overestimate PIP, because such adjustments need to be made for use in different populations. Although test-retest reliability is thought to be acceptable, it is less consistent than measures that directly record isovolumetric pressure (Tan et al., 2003).

Isovolumetric pressure can be measured directly by mechanically obstructing the flow of urine (Sullivan and Yalla, 2007)**. This can be achieved through either (1) a stop test, interruption of urine flow after it has begun, or (2) a continuous occlusion test, in which the urine outflow is blocked before and during the course of the voiding contraction.**

There are two types of stop test: a voluntary stop test, in which the patient voluntary contracts the urethral sphincter, and a mechanical stop test, in which the bladder outflow is occluded by the investigator (e.g., by tugging a catheter balloon against the bladder neck). These techniques correlate well with each other in both sexes (Tan et al., 2003), but the voluntary stop test tends to produce a lower value for isovolumetric pressure by approximately 20 cm H_2O. This is probably explained by the reflex detrusor inhibition induced by urethral sphincter contraction (Sullivan et al. 1995). The voluntary stop test is difficult and sometimes impossible to conduct in patients with urethral sphincter weakness. The continuous occlusion testing has greater test-retest reliability and allows assessment of sustainability of contraction, although the consequence is that a representative flow measurement during that particular contraction is not obtained. Although it correlates well with the ability of the bladder to empty (Sullivan and Yalla, 1996), continuous occlusion is potentially painful and has found little applicability outside of a research setting.

Overall, the different criteria for assessing contraction strength are not in concordance when applied to patients with DUA with a reported variation in the diagnosis of DUA between 5% and 55% when applied to patients with non-neurogenic LUTS (Jeong et al., 2017). Thus it is imperative in the future to develop a standardized methodology and criteria, and this is currently the subject of ongoing work.

Detrusor Contraction Speed

A bladder that contracts more slowly could in theory result in clinical symptoms, although this is not part of the ICS definition. A reduction in detrusor shortening velocity, calculated by the following formula:

$$\mathrm{Vdet} = Q/2[3/(V + Vt)/4\pi]0.66$$

(where Q represents the flow rate [mL/sec], V represents bladder volume [mL], and Vt represents the volume of noncontracting bladder wall tissue) was found to precede reduction in WF in a series of longitudinal studies in both males and females (Cucchi et al., 2007, 2008, 2010).

Detrusor Contraction Duration

A detrusor contraction of reduced duration is suggested by the ICS as part of the definition of DUA (Abrams et al., 2002); however, the limits of a normal voiding detrusor contraction are not defined. There are only a few studies that assess contraction duration as a urodynamic parameter. In a study of men with BPH, unobstructed patients with poor contractility actually had significantly longer contraction durations than those with no obstruction and normal contractility (Ameda et al., 1998). It is likely that the contraction duration reflects the underlying pathophysiologic mechanisms—for example, an early termination of the micturition reflex could presumably lead to a shorter duration. **A standardized method for measuring duration of the detrusor contraction is needed before any conclusions can be reached.**

Bladder Sensation

An assessment of bladder sensation is clearly relevant to the evaluation of DUA because the afferent nerves play such a central role in the initiation and maintenance of a detrusor contraction. An analysis of urodynamic traces of 1329 men highlighted that patients with DUA had decreased bladder sensation compared with groups with LUTDs (Jiang and Kuo, 2017b). **Assessment of**

bladder sensation is most commonly undertaken using the patient's perceptions of bladder filling (first sensation, first desire, strong desire, and capacity).

Thresholds in normal individuals are available (Wyndaele, 1998), although this method can be criticized because patients may report bladder sensation even when the bladder is not being filled (De Wachter et al., 2008; Erdem et al., 2004); as with any subjective measure, there is substantial individual variation because of the circumstances of a UDS and the anxiety level of the study subject. Testing sensory responses to the passage of electrical current through the bladder wall (current perception threshold testing) may provide a more objective measure but is clearly a rather invasive approach and is as yet an unvalidated research technique.

Ambulatory Urodynamics

Patients often fail to void during UDS because of anxiety or a bashful bladder. It is thought this arises as a result of poor pelvic floor relaxation and reflex detrusor inhibition. Alternatively the patient may have true DUA or acontractile detrusor. A careful history is usually sufficient to differentiate the two situations. Where doubt exists, ambulatory UDS may be useful (Rosario et al., 2000). van Koeveringe et al. (2010) demonstrated that 84% of patients who failed to generate a detrusor contraction during standard UDS had evidence of demonstrable contraction during an ambulatory study. It must, however, be borne in mind that there is no accepted standardization of ambulatory urodynamic criteria, as they often differ significantly from what is seen on a standard urodynamic test when carried out sequentially in the same patient. Nevertheless, in a recent study of 239 patients (71 male and 168 female), the largest subgroup of patients (79; 33%) who underwent ambulatory urodynamic monitoring did so based on clinical suspicion of an acontractile bladder (Rademakers et al., 2017). It was evident that 66 of these patients (83.5%) still showed contractions on ambulatory urodynamics.

Key Points: Diagnosis

- There is no published consensus on the diagnostic criteria for DUA.
- Most available criteria focus on the strength of contraction as determined by

the Pdet during UDS.

- Several indices and formulas to estimate isometric detrusor strength are available, most of which are unvalidated and are not applicable to all patient groups.
- Urodynamic stop and occlusion tests are more reliable but may be painful and impractical.
- The significance of other aspects of detrusor contraction such as speed and duration is unclear.

Management

The goals of managing the patient with DUA are to improve symptoms and quality of life and reduce the risk for complications of impaired bladder emptying. These include urinary tract infections (UTIs), bladder stones, ureteric reflux leading to back-pressure on the upper urinary tract, and skin damage from urinary overflow incontinence associated with chronic retention. There is a profound lack of effective treatments to improve detrusor function and thereby facilitate bladder emptying. Thus management commonly entails bladder drainage techniques (e.g., catheterization) or therapies aimed at reducing bladder outlet resistance, for example, by relaxing the external urethral sphincter mechanism. The clinical approach and therapies that are available in contemporary clinical practice and potential experimental approaches are reviewed in the next sections (Fig. 118.7).

	In routine clinical use	Experimental	Not recommended
Drainage	Time voiding/double voiding Catheterization Urine diversion		Compression Reflex voiding Valsalva voiding
↓ Outlet resistance	Pelvic floor physiotherapy and biofeedback α-Blockers Muscle relaxants Bladder outlet surgery	Intrasphincter botulinum toxin	
↑ Detrusor function	Sacral neuromodulation Anterior sacral root stimulator	Intravesical prostanoids Intravesical electrotherapy Detrusor myoplasty Reduction cystoplasty	Anticholinesterase Muscarinic agonists

FIG. 118.7 Management options in detrusor underactivity.

Initial Assessment

The assessment of patients with symptoms suggestive of DUA entails routine urologic evaluation (bladder diary, digital rectal examination, urinalysis, uroflowmetry, PVR estimation using ultrasonography) and neurologic assessment (sacral dermatomes, anal tone, the bulbocavernosal reflex, lower limb reflexes). Neurologic deficits require further specialist evaluation; magnetic resonance imaging of the spine is commonly performed in particular to assess the lumbar spinal cord and cauda equina. A careful drug history should be taken to identify medications that impair bladder contractility (agents with anticholinergic or opioid effects) (see Box 118.1) or that increase outlet resistance (e.g., α-adrenoreceptor agonists). Fecal impaction/constipation may contribute to poor bladder emptying by a direct obstructive effect, and, if identified, its treatment may facilitate improved

bladder emptying (Charach et al., 2001).

Conservative Management

Behavioral interventions in patients with DUA aim to reduce the symptoms and complications of incomplete bladder emptying. Scheduled voiding can be instituted to increase the frequency of voids in patients with sensory impairment. Double voiding to improve bladder emptying may help reduce bothersome frequency, and patients often use this strategy before seeking treatment. Bladder expression techniques such as Valsalva voiding or the Credé maneuver are used in only very specific neurogenic situations (i.e., DUA with incompetent sphincter) and are otherwise not recommended because of the risk for generating high vesical pressure, causing vesicoureter reflux or causing reflux into the prostate and seminal vesicles.

Pelvic floor physiotherapy and biofeedback have been used to successfully treat children and adults with dysfunctional voiding (de Jong et al., 2007; Minardi et al., 2010)**. In this group, poor relaxation of the pelvic floor muscles and the external urethral sphincter mechanism may obstruct urine flow and cause reflex inhibition of detrusor contraction.** In a study by van Koeveringe et al. (2010), 24% of patients with acontractile detrusor on conventional UDS who subsequently demonstrated contractility on ambulatory studies were successfully treated with physiotherapy.

ISC is the preferred method of establishing bladder drainage in patients with problematic high PVR. Provided cognition and dexterity are adequate, this method is safe and effective, with lower infection rates than with indwelling catheters. Specific problems include urethral bleeding (one-third of patients) (Webb et al., 1990) and production of false passages. Additionally, the technique may be time-consuming and socially restricting; some patients may be unable to overcome the psychological barriers such as a fear of inflicting harm or infection (Mangnall, 2012). An indwelling urethral catheter is best avoided in the long term, and in this context a suprapubic catheter is the best long-term option in patients unwilling or unable to perform ISC.

Pharmacotherapies

Parasympathomimetics for Underactive Bladder

Acetylcholine is the principal neurotransmitter mediating bladder contraction, acting on muscarinic (M_3) receptors. **Parasympathomimetic agents, including direct muscarinic receptor agonists or anticholinesterases, have been used with the aim of increasing bladder contractility. Bethanechol and carbachol, the most common compounds studied, are quaternary amines that are selective for the muscarinic receptor but not receptor subtype selective.** In mechanistic terms, these compounds are more likely to be effective if the problem is reduced or absent contractile stimulus (e.g., reduced efferent input, impaired acetylcholine release from parasympathetic nerves, increased acetylcholine breakdown). Anticholinesterases (e.g., distigmine) would require the presence of at least some endogenous acetylcholine, to amplify its effect. Conversely, if the underlying cause is reduced tissue responsiveness to stimulation (e.g., detrusor muscle cell dysfunction, bladder wall fibrosis), parasympathomimetics are less likely to benefit. Similarly, if the problem is loss of the detrusor muscle, no pharmacotherapy is likely to be effective.

The efficacy of parasympathomimetics has been assessed in a small group of heterogeneous studies, mainly for the prevention and treatment of postoperative urinary retention. A systematic review of this literature (Barendrecht et al., 2007) found that only 4 of 10 randomized clinical trials included (two of the four in patients with DUA) showed a significant benefit over placebo. However, all of these studies could be considered to be underpowered. Bethanechol was used in all four (dose of 10 to 50 mg up to four times daily). A further three studies failed to show any advantage with use of this agent. One study found that distigmine (5 mg) actually increased PVR compared with placebo. It was concluded that there is little, if any, benefit in using parasympathomimetics.

When bethanechol is given to neurologically normal individuals, it causes a rise in bladder wall stiffness and sensory perception (De Wachter and Wyndaele, 2001). De Wachter and Wyndaele (2003) also noted that women with DUA responding to bethanechol demonstrated significant reductions in bladder sensory thresholds. Hence, intact sensory pathways may be a prerequisite for improvement in voiding with muscarinic agonists, which may explain their lack of efficacy in unselected groups. Alternatively, it could be that the doses used are simply too low because of the concern with side effects. **Parasympathomimetics are associated with significant dose-dependent systemic side effects, including nausea, bronchospasm, abdominal cramping, diarrhea, increased salivation, flushing, and visual disturbances. A rare but potentially lethal side effect is severe cardiac depression resulting in cardiac arrest. In contemporary practice, parasympathomimetic agents**

are generally avoided because of their questionable efficacy and potentially serious side effects.

α-Adrenoreceptor Antagonists

α-Adrenoreceptor antagonists have been used to reduce bladder outlet resistance in children and adults with both neurogenic bladder and dysfunctional voiding. Chang et al. (2008) studied the use of tamsulosin (0.2 mg) in 52 women with DUA (Pdet@Qmax <10 cm H_2O). The authors found that 38.5% had a greater than 50% improvement in voiding LUTS, 53.8% had a greater than 30% improvement in Qmax, and 32.7% were judged to have had a good therapeutic response. **Combination therapy with an α-adrenoreceptor antagonist and a parasympathomimetic has long been considered a therapeutic possibility** (Khanna and Gonick, 1975). In a prospective single-blind randomized study of 119 patients with DUA, urapidil alone did not result in a reduction in Qmax in either sex and led to a reduction in PVR in women only (Yamanishi et al., 2004). By contrast, a combined regimen of urapidil (60 mg) with either bethanechol (60 mg) or distigmine (15 mg) led to significantly improved flow rates (by 2.66 mL/sec in women, $P < .01$, and 4.33 mL/sec in men, $P < .05$) and significantly reduced PVR in women (by 54.1 mL/sec, $P < .01$) (Yamanishi et al., 2004).

Prostanoids

Prostanoids are a subclass of signaling molecules that may be implicated in the micturition reflex. The efficacy of prostanoids in treating DUA is not clear. Most clinical studies have evaluated the effect of intravesical prostaglandin (PG) instillation in the prevention of postoperative urinary retention.

There are five principal endogenous prostanoids (PGE_2, $PGF_{2\alpha}$, PGI_2, PGD_2, and thromboxane A) that are all synthesized in the bladder wall and released into the general circulation when the bladder is stretched (Maggi, 1992; Rahnama'i et al., 2012). Detrusor contraction in response to acetylcholine and adenosine triphosphate stimulation is enhanced by prostanoid production. Conversely, nonsteroidal anti-inflammatory agents (inhibitors of prostanoid synthesis) cause a loss of tone in the isolated bladder that is reversed with the administration of prostanoids. $PGF_{2\alpha}$, PGE_1, and PGE_2 all enhance detrusor contraction; PGE_1 and PGE_2 cause urethral relaxation, and $PGF_{2\alpha}$ results in urethral contraction (Rahnama'i et al., 2012).

The clinical studies conducted to date have demonstrated mixed outcomes (Bergman et al., 1992, 1993; Koonings et al., 1990; Tammela et al., 1987; Wagner et al., 1985); however, a recent pooled analysis of the results of two randomized trials assessing PGE_2 and a third assessing $PGF_{2\alpha}$ demonstrated a statistically significant association between instillation and successful voiding (risk ratio 3.07) (Buckley and Lapitan, 2010). Both PGE and PGF series also stimulate contraction of the uterus, a potential side effect of treatment (O'Brien, 1995).

Future Prospects in Pharmacotherapy

In the absence of any effective compound, there are several avenues aimed at increasing bladder contractility that can be explored, as follows:

- Parasympathomimetics could yet be an option; however, their side-effect profile is concerning. Development of a bladder-specific agent could avoid these effects permitting dose escalation. However, this is unlikely based on contemporary knowledge.
- Novel muscarinic receptor manipulation such as postsynaptic allosteric receptor enhancement or the presynaptic M_2-receptor antagonist could be promising.
- Exogenous prostanoids require further investigation; agents with selectivity for the urinary tract over the uterus and gastrointestinal tract are under development; however, whether they will be effective if taken orally is an important question.
- Agonists of transient receptor potential (TRP) channels, such as TRPV4 agonist GSK1016790A, can increase contractility and are worthy of further investigation.
- Treatments of analogous conditions affecting other organ systems, such as cardiac inotropes in cardiac failure or prokinetics for intestinal dysmotility, could provide alternative options to increase contractility.
- Improving bladder sensation using sensory sensitizers could hypothetically help patients with impaired afferent signaling.

To develop effective drug therapies, there is a need to better understand the pharmacologic principles that underpin normal detrusor contraction and the mechanisms of detrusor dysfunction underlying DUA. This is the subject of ongoing work at present with no new candidate drugs available in clinical trials at present.

Electrical Stimulation

A variety of electrical stimulation techniques have been applied in DUA of different causes. Brindley et al. (1982, 1986) developed the sacral root stimulator for patients with complete spinal cord injury to activate the anterior sacral roots and achieve volitional bladder emptying. For the procedure to be successful, there is a need for intact peripheral efferents and the absence of myogenic dysfunction. This is confirmed by the presence of reflex detrusor contractions on bladder filling preoperatively. The anterior sacral roots are stimulated through an implantable receiver, stimulation wires, and external transmitter. Stimulation also activates urethral somatic efferents; this is overcome by using intermittent stimulation patterns that exploit the longer relaxation time of smooth muscle compared with skeletal muscle to generate a sustained detrusor contraction with short intermittent periods of sphincter contraction. Clinically, this results in an interrupted void pattern. Sauerwein (1990) subsequently modified the technique by combining it with total sacral root rhizotomy, thereby abolishing all reflex activity.

Katona and Berenyi (1975) popularized the technique of applying electrical current to the bladder wall through a transurethral electrode in 1958, termed *intravesical electrotherapy* (IVE). The bladder is filled with saline, and current is passed through an electrode (cathode) at the tip of the catheter; the circuit is completed by a neutral electrode applied to the skin in an area of normal sensation. Daily sessions of stimulation are undertaken, usually of 1 hour or more, with 10 to 15 sessions considered a trial period.

Animal experiments have shown that IVE activates mechanosensitive bladder afferents (myelinated Aδ fibers) and, as a consequence, central reflex activation of the detrusor (Ebner et al., 1992)**. It is postulated that repeat activation of this pathway upregulates its performance during bladder filling and volitional voiding, resulting in improved sensation and emptying. On this basis, where the underlying cause is complete denervation or bladder wall fibrosis, IVE is considered unlikely to be**

successful.

IVE has been studied primarily in the pediatric age group with some encouraging results, but is still considered a controversial therapy. There is considerable heterogeneity in inclusion criteria and technical aspects, and most studies include only small numbers, limiting definitive conclusions as to efficacy. In children with both neurogenic and idiopathic DUA, voiding was normalized after treatment in as many as 85% of cases (Gladh et al., 2002). In adults with predominately neurogenic DUA, 39% of those without a detrusor contraction and 75% without bladder sensation before treatment experienced a restoration of these parameters (Primus et al., 1996). Several studies have failed to show benefit, including the only sham controlled randomized prospective study (Boone et al., 1992). Moreover, IVE often is undertaken alongside an intensive bladder training/biofeedback regimen, which may partially explain the favorable outcomes (Madersbacher, 1990). **Although not associated with significant complications (except a small risk for UTI), its principal limitations are the significant time and resource requirements. An average of 47 sessions was required for a durable effect in a cohort of children followed for 10 years after treatment** (Kaplan, 2000).

Sacral neuromodulation (SNM) was first introduced over 30 years ago by Tanagho and Schmidt (1982)**. It has been used with good efficacy in a group of patients with nonobstructive urinary retention and DUA** (Everaert et al., 1997; Swinn et al., 2000). It is postulated that abnormal afferent signals generated from the urethral sphincter (because of pelvic floor/sphincter disorders) have an inhibitory effect on bladder afferents at the level of the sacral spinal cord, preventing their transmission in the periaqueductal gray and higher brain centers. **SNM is thought to inhibit urethral afferent signals and allow restoration of normal afferent flow to the brain and the resumption of normal bladder sensation and detrusor contractions.** A direct effect on bladder efferents is possible but less likely (DasGupta and Fowler, 2004). SNM has also shown potential in treatment of patients with DHIC, who pose a particular treatment challenge due to the co-existence of DOA and DUA, with the treatment of one aspect often negatively affecting the other. It is evident that sacral neuromodulation can have some effect if there is underlying detrusor function. The crucial aspect that requires clarification is in patients with a combination of detrusor underactivity and BOO. Recent work has aimed at providing a diagnostic approach to help with this differentiation (Rademakers et al., 2017).

An alternative form of electrical stimulation, transcutaneous electrotherapy (using skin electrodes) was recently studied in a small randomized controlled trial in children alongside urotherapy (Kajbafzadeh et al., 2016). Though significant improvements in voiding time, bladder capacity, and flow rate were noted in the active treatment group, the lack of sham treatment group is a significant limitation.

Botulinum Toxin

Botulinum neurotoxin A (BoNT-A) injected into the urethral sphincter has been used to reduce outlet resistance and improve bladder emptying in patients with detrusor-sphincter dyssynergia (Dykstra et al., 1988; Phelan et al., 2001; Schurch et al., 1996)**. The potential rationale for its use in DUA is to relax the urethral sphincter mechanism, thereby overcoming reflex inhibition of detrusor function** (Park et al., 1997)**, or to facilitate Valsalva-induced voiding.**

Kuo (2003) reported the results of urethral BoNT-A (50 U in 4 mL of normal saline) in 20 patients with DUA of mixed causes. The toxin was injected cystoscopically in men and periurethrally in women. Seven patients who previously required indwelling catheters could void with low PVRs (≤150 mL). In the 7 patients performing ISC at baseline, it could be stopped or reduced in frequency after injection. The same author also reported the effects of urethral BoNT-A (50 U or 100 U in 4 mL and 8 mL of normal saline, respectively) in 27 patients (5 men and 22 women) with idiopathic DUA (low or no Pdet and Qmax of <10 mL/sec and PVR >150 mL) (Kuo, 2007a). An increase in Pdet and Qmax with a decrease in PVR occurred in 13 patients (48%), all of whom could void without abdominal straining. Analysis of baseline characteristics identified the responders as having significantly better bladder sensation. Patients with evidence of poor sphincter relaxation before treatment were more likely to improve (87%) compared with patients who had DUA only (33%) or DHIC (30%).

The evidence available suggests that the action of BoNT-A, when injected into the urethral sphincter mechanism, is short-lived, and to date no adequate clinical studies have been conducted to evaluate the appropriate dose. In this context, it is not licensed for use and cannot be used outside of a clinical trial setting.

Surgery

Bladder Outlet Surgery

The role of bladder outlet surgery in the management of men with non-neurogenic DUA is a controversial topic in which there is a lack of high-level evidence to guide clinical decision making. A recent meta-analysis assessing a total of 10 comparative studies assessing transurethral surgery found that those with DUA had significantly poorer improvement in I-PSS (International Prostate Symptom Score) and maximal flow rate in comparison with patients who had preserved contractility (Kim et al., 2018). Both groups showed similar changes in quality-of-life score, and PVR volumes were equivalent.

Although the findings of such meta-analysis confirms the experience of most urologists that overall such patients do less favorably, it is important to differentiate between two common clinical scenarios from a practical point of view: the patient with DUA with a low or minimal PVR whose primary complaint is symptoms, and the patient with DUA who is catheter-dependent (i.e., chronic retention). In the former, although BOO cannot be definitively excluded, because of the limitations of urodynamic analysis discussed earlier, it is generally less likely to be significant as the patient is able to empty the bladder with a low Pdet. In this situation, outlet surgery is generally considered to be unlikely to significantly improve voiding LUTS. This supposition is supported by a study that followed 22 men with DUA treated with TURP for a mean of 11.3 years (Thomas et al., 2004). The majority of patients underwent TURP on the basis of symptoms (3 of 22 after acute retention). There was no significant improvement in any symptoms. A small reduction of questionable clinical significance in the BOO index (BOOI = Pdet@Qmax − 2 Qmax) did occur but was not associated with an improvement in flow rate or voiding efficiency. **It can be concluded that when compared with patients who have DUA undergoing conservative treatment, outlet surgery confers no significant improvement in symptoms or urodynamic parameters.** Other studies with shorter follow-up support these findings (Javle et al., 1998; Rollema and Van Mastrigt, 1992).

In the situation in which the patient with DUA is catheter-dependent and has arguably reached a later stage of detrusor decompensation, even less evidence is available as to the benefit of outlet surgery. Surgery is performed with the aim of reducing outlet resistance enough to permit bladder emptying, albeit the flow rate and PVR rarely return to normal in this scenario. Predictors of poor outcome include low voiding pressures (<45 cm H_2O) (Ghalayini et al., 2005), older age (>80 years), and high residual volume (>1500 mL) (Djavan et al., 1997). **Although the limited evidence suggests men with DUA and chronic retention do less favorably after bladder outlet surgery** (Ghalayini et al., 2005)**, a significant proportion resume spontaneous voiding** (Monoski et al., 2006)**. In the absence of any other effective treatments, some advocate surgery in the younger, medically fit patient who wishes to become catheter free**.

The use of urethral dilation for women with DUA and significant residuals has been advocated but lacks an adequate evidence base to permit clear conclusions to be drawn (Basu and Duckett, 2010)**. Resection or incision of the bladder neck in women with DUA is not recommended, because this may lead to significant problems with either incontinence or bladder neck stenosis.**

Urinary Diversion

Because of the general acceptability and safety of both ISC and indwelling catheterization techniques, urinary diversion is rarely performed for DUA outside of the neurogenic population. When urethral clean intermittent catheterization is not possible and the patient wishes to avoid a suprapubic catheter, as is often the case in young women with idiopathic urinary retention refractory to SNM, a continent catheterizable stoma can be created. An incontinent diversion (e.g., ileal conduit) is occasionally performed when there are signs of renal deterioration resulting from obstruction to the intramural ureters secondary to a thick-walled bladder.

Reconstructive Surgery

Few reports of reconstructive surgical procedures for DUA are available. Stenzl et al. (1998) reported the first series of latissimus dorsi detrusor myoplasty (LDDM) in patients with DUA in 1998. The muscle is harvested, and its pedicle is anastomosed to the inferior epigastric vessels, with the nerve coapted to the intercostal branch. The muscle is wrapped in a spiral configuration around the bladder, covering over three-fourths of its surface. It is then anchored to the pelvic floor fascia and ligaments. The long-term outcomes of this technique in 24 catheter-dependent patients with acontractile detrusor have been reported (Gakis et al., 2011). Seventeen patients recovered the ability to void (mean PVR

= 25 mL). The mean bladder contractility index increased from 20.1 ± 7.6 to 176.2 ± 25.4 ($P < .001$). Complications occurred in one-third of patients, including thromboembolism, pelvic abscess, and wound infection, though there were no long-term problems. Rectus abdominis detrusor myoplasty was also reported as a potentially less morbid and complex intervention than LDDM. In five patients with spinal cord injury and DUA or acontractile bladder, complete spontaneous voiding was possible, with no major complications at over 1-year follow-up (Agarwal et al., 2018). Reconstructive surgery for DUA remains investigational at present.

Partial cystectomy (or reduction cystoplasty) has been reported in a few series as an alternative approach (Klarskov et al., 1988; Weinberg et al, 1974). However, there are no recent reported studies, and it is no longer considered in contemporary practice.

Regenerative Medicine

Although tissue engineering of whole bladders has been investigated for over a decade and resulted in a small clinical study with some success (Atala et al., 2006), such bladders can only fulfill a storage function because of the difficulty of recreating the complex neural innervation to enable volitional emptying. An alternative approach is to inject stem cells at various sites to restore bladder function. Several studies investigating different cell types to treat bladder dysfunction in animals are available. These studies follow the scheme of using a model of underactive bladder, injecting stem cells in the bladder or at the site of damage to the neural innervation, and then performing urodynamic assessment of bladder contractility. Some of these studies have shown an improvement in contractility (Chen et al., 2012; Nishijima et al., 2007). Recently, a study in which autologous muscle-derived stem cells were injected in the bladder wall of a 79-year-old male with DUA reported some improvement in voiding parameters at 1 year follow-up, however the patient still needed to perform ISC (Levanovich et al., 2015). To conclude, the major barriers to overcome include our incomplete understanding of the structure and function of the lower urinary tract and the inevitable concern regarding whether muscle cells injected into the bladder wall will in fact be able to acquire a functional innervation and hence contribute to wall function in a meaningful fashion.

Key Points: Management

- There are no effective pharmacotherapies for the treatment of DUA.
- Parasympathomimetic agents have questionable efficacy, are associated with potentially fatal systemic effects, and are not used in routine practice.
- Intravesical electrotherapy has shown promising results in restoring detrusor contraction; however, it is time- and resource-consuming.
- SNM is effective in restoring voiding in patients with DUA associated with urethral sphincter/pelvic floor disorders.
- Bladder outlet surgery has a high risk for failure in men with DUA not reliant on catheters. Men with DUA and chronic retention dependent on catheter drainage experience poorer outcomes than those with normal

detrusor function; however, they still may benefit from surgery.

Conclusions

DUA is a common problem that can pose a difficult challenge for both patients and physicians because of the lack of simple and effective treatments. This problem has received little attention in clinical and basic science research in comparison to other common LUTDs such as OAB and DOA. Defining the problem in symptom-based terms is difficult because there is a wide spectrum of manifesting symptoms, underlying clinical conditions, and absence of accurate noninvasive markers. Clinical studies suggest that the problem is highly prevalent in both men and women with LUTS presenting to urologists. A variety of causes are implicated, affecting all aspects of the micturition reflex. There is a lack of any simple and effective treatments. Preserved bladder sensation appears to predict better responses to treatment. There is a need for a greater understanding of the mechanisms governing normal detrusor contraction and how these are affected by disease. Until this is achieved, it will be difficult to develop compounds that enhance detrusor strength and duration of contractility or enhance bladder sensation. In the future, developments in regenerative medicine, stem cell therapy, and gene therapy may provide interesting avenues for further research, but a prerequisite for this will be to develop a better understanding of both normal structure and function of the lower urinary tract and the way in which this is altered in cases of DUA.

Nocturia

Stephen D. Marshall MD, Jeffrey P. Weiss MD, FACS

Nocturia, defined as waking because of the desire to void during intended sleep, can be the result of an abnormality in the genitourinary tract or a symptom of an underlying medical condition. Because of its multifactorial nature, uncovering the etiology of a patient's nocturia and treating it appropriately can be a diagnostic and therapeutic challenge for the urologist. A systematic approach, including a thorough history and physical examination, is essential to determine conditions contributing to nocturia. Therapeutic options are numerous and include conservative/behavioral management, pharmacotherapy, phytotherapy, and invasive procedures. Tailoring appropriate therapy to accurate diagnosis should lead to effective treatment and patient satisfaction.

Rationale for Evaluation and Management

Nocturia Is Bothersome
